## ABSTRACT

The effect of relative humidity (RH) on OH uptake by surfaces of tropospheric importance was investigated. Due to diffusion limitation conditions, experiments were performed with parallel reactors packed with beads and using a surface dilution technique. A virtual cylindrical reactor approximation was developed to further quantify and confirm the reaction probability of OH for the surfaces of interest. While OH exposure of hydrophobic organic surfaces (paraffin wax, pyrene, and methane soot) did not result in measurable change in their relative hydrophilic properties, the presence of water vapor enhanced the OH reactivity on a hydrophilic organic surface (glutaric acid). The RH effect on OH uptake by sea salt and its components was dependent on the nature of the cations. Redistribution of surface ions under humid environments caused changes in pH on the inorganic surfaces, thereby influencing the rate-determining step in the reaction mechanism of heterogeneous OH uptake. This segregation effect explains why the RH effect on OH uptake by sea salt is determined by  $\text{MgCl}_2$  rather than  $\text{NaCl}$ . Experimental evidence suggests that adsorbed water on the surfaces of  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$  is responsible for enhancement in OH reactivity with mineral dust surfaces under high humidity conditions.

Mass spectra of the gas-phase species produced from the heterogeneous reaction of OH with  $\text{NaCl}$  were obtained in order to characterize the reaction products and the kinetic mechanism. Evidence for gas-phase  $\text{HCl}$ , supplemented with kinetics modeling and experiments on heterogeneous  $\text{O}_3$  reactivity strongly suggest that  $\text{Cl}_2$ , sole product of the heterogeneous reaction, transforms to  $\text{HCl}$  in the presence of H radicals. The  $\text{Cl}_2$  yields per OH collision were determined to be 0.020 and 0.022 at 0% and 6% of RH, respectively. Enhancement in  $\text{Cl}_2$  production was observed under wet conditions, consistent with a measured chlorine deficit on the  $\text{NaCl}$  surface. Two alternate reaction mechanisms are proposed to describe the heterogeneous OH uptake by  $\text{NaCl}$ .

## Acknowledgements

I would not say that the last five years were easy for me. However, I could keep moving forward thanks to many people, and finally did a wonderful job.

First, I want to thank my advisor, professor Mario Molina, for his invaluable advice, guidance, and encouragement. It was a great experience to work in his group. Even though he is one of the busiest scientists in the world, he has never been reluctant to share his time with me whenever I need him. I also admire his humble attitude. I remember that he delivered us mails in person going up and down the stairs in the Green Building. He is the only delivery man who won the Nobel prize. I appreciate the advices and helps from my former advisor, professor Jong-Ho Choi in Korea University. He is the person who initiated my enthusiasm for the physical chemistry.

Working at the Molina group let me have many best friends. Thanks to my best Russian friend, Andrey Ivanov. He always welcomed and gave invaluable advices to solve the problems that I had. He also told me many Russian proverbs to encourage me when I was depressed. Kirsten Johnson, my best American friend, shared a lot of things including her experience about science and even her cookies. Thank you so much for your kindness, Kirsten. Ingrid Kohl is my best Austrian friend that I have to emphasize her helps. She was willing to do the experiment with me when I just joined the group. Even though it was not so long before she left for Austria, she made me familiar with the experiment by sharing her precious experience. Thanks to the other best friends: Rainer Volkamer, Jun Noda, Miguel Zavala, Elizabeth Fitzgerald, Edward Dunlea, Gregory Poskrebshev, Philip Sheehy, and Van Tran. I also express my thanks

to Luisa Molina.

Thanks to my Korean friends: Hohjai Lee and his wife, Li Zhang, Keehyun Choi, Changsik Song, Jeongkwon Kim, Jae-Gook Lee, Byungkwon Min, Chankyu Joo and Mi Hee Lim. I could not have survived from the tough five years without you all.

My best thanks to my parents and my brother. I can not imagine how much I owe from them in my life. My dad and mom always trust me to give the best supports. I have been learning from them almost everything that I must know to live as a good citizen, a good son, and a good parent. They also provided me Jong-Sung. He is not only my brother, but also my friend and supporter. It is wonderful to be your son and brother. I also give my appreciation to Jeong-Eun Hong, my sister-in-law.

Finally, no words can be enough for my wife, Eunsook, and my two sons, June and Sean. This is for you.

## **Chapter 1**

# **Introduction**

## 1.1. OH Radicals in the Troposphere

As a key oxidant, the hydroxyl radical (OH) is involved in numerous reactions with tropospheric constituents. One of the most important examples of its involvement is the OH-initiated oxidation of volatile organic compounds (VOCs), such as aldehydes, alkanes, and alkenes, which eventually leads to their removal from the troposphere. Ozone ( $O_3$ ) abundance in the troposphere has been also established to be mostly determined by its catalytic cycle reactions with  $HO_x$  ( $= OH + HO_2$ ) with indirect involvement of  $NO_x$  ( $= NO_2 + NO$ ) as is schematically described in Figure 1.1.

**Figure 1.1** Radical cycling reactions of OH in the troposphere

The production of OH is initiated by the photodissociation of ozone molecules under the effect of ultraviolet (UV) radiation to generate electronically excited oxygen atoms followed by reaction with water vapor.

The newly formed OH is rotationally and vibrationally excited [Saunders *et al.*, 1992, Park *et al.*, 2002, 2003], which is efficiently deactivated by collision with nitrogen and oxygen molecules [D'Ottone, 2004].

Another source of OH is the fast reaction between HO<sub>2</sub> and NO with a rate constant of  $8.8 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Atkinson *et al.*, 2004].

Photolysis of gaseous nitrous acid (HONO) is the other major source producing directly OH.

Although the contribution of each possible source of OH, and hence, the OH concentration, depend on the actinic flux, concentrations of ozone, water vapor, nitrogen monoxide (NO), nitrogen dioxide (NO<sub>2</sub>), and HONO, a global average [OH] in the troposphere ranges from several  $10^5 \text{ molecule cm}^{-3}$  at nighttime to  $5 \times 10^6 \text{ molecule cm}^{-3}$  at daytime [Seinfeld *et al.*, 1998]. OH is found to be a short-lived radical with a lifetime of approximately one second even under clean atmospheric conditions [Heard *et al.*, 2003]. The main sinks of OH in the gas phase are its reactions with carbon monoxide (CO) and methane (CH<sub>4</sub>) [Seinfeld *et al.*, 1998].

and,

## 1.2. Discrepancy between Models and Field Measurements of OH Concentrations in the Troposphere

Although establishing models to account for the measurements is necessary, consistent overestimations of the atmospheric models in OH concentrations have been reported by field measurements. These overestimates range from 20% [Poppe *et al.* 1994] to a factor of 4 [Eisele *et al.*, 1994], as summarized in Table 1.1. Such discrepancies indicate that there are missing sinks of OH, which are unaccounted in the models. It has been suggested that gas phase reactions of OH with unmeasured biogenic hydrocarbons, such as isoprene [Eisele *et al.*, 1994] and  $\beta$ -pinene type species [McKeen *et al.*, 1997], could be considered as one of possible missing sinks.

**Table 1.1** Summary of model overestimations of [OH]

Campaign	Model Overestimation of [OH]	Reference
Deuselbach (1983) and Schauinsland (1984)	20%	[Poppe <i>et al.</i> 1994]
Fritz Peak, Colorado (1991)	Factor of 4	[Eisele <i>et al.</i> , 1994]
Mauna Loa Observatory (1992)	Factor of 2	[Eisele <i>et al.</i> , 1996]
Fritz Peak / Idaho Hill (1993)	51%	[Crosley, 1997] [McKeen <i>et al.</i> , 1997]
Mace Head (1996)	40%	[Carslaw <i>et al.</i> , 1999]
MCMA-2003 (2003)	30%	[Shirley <i>et al.</i> , 2006]

### 1.3. Heterogeneous Losses of OH as Additional Missing Sinks

In addition to the gas phase reactions with unmeasured biogenic hydrocarbons, OH heterogeneous loss on aerosol particles, is not included currently in the models, and has also been suggested to explain the discrepancies. Historically, OH heterogeneous reactions have been largely overlooked due to the short lifetime of OH in the troposphere. However, the heterogeneous sink of OH can be important under certain conditions in polluted air and liquid cloud droplets. For example, Saylor *et al.* [1997] estimated that the fraction of heterogeneous loss under urban conditions ( $[\text{NO}_x] = 10$  ppbv, and  $[\text{VOC}] = 10^8$  molecule  $\text{cm}^{-3}$ ) would be 30% of the gas phase loss at  $10^5$  particle/ $\text{cm}^3$  of aerosol density and 0.1 of an reaction probability for  $\text{HO}_2$  ( $\gamma_{\text{HO}_2}$  defined in the section 1.4), and even 190% at the same density and  $\gamma_{\text{HO}_2} = 1$ , while it would be negligible at low aerosol density ( $<10^3$  particle/ $\text{cm}^3$ ). In this case, knowledge of OH heterogeneous chemistry, including reaction mechanisms and their rates, is required to improve modeling accuracy.

Heterogeneous radical reactions become important even under extremely clean conditions. This is because of slower radical sinks through gas-phase reactions with organics or  $\text{NO}_x$ , and therefore, the contribution of heterogeneous reactions to total radical loss becomes more significant. The remote marine boundary layer is an example where the concentrations of VOC's and  $\text{NO}_x$  are low and that of aerosols is moderate; under these conditions the contribution of the OH heterogeneous chemistry can be greatest.

As a first demonstration, Isaksen and Crutzen [1977] included a heterogeneous loss channel for OH and  $\text{HO}_2$  (hydroperoxyl) radicals into a high sensitivity to  $\text{HO}_x$  ( $= \text{OH} + \text{HO}_2$ ) photochemical model using high reaction probability values for OH and

HO<sub>2</sub> radicals ( $\gamma_{\text{OH}} = \gamma_{\text{HO}_2} = 1$ ). However, subsequent experimental determinations of the reaction probabilities showed that these values are usually much smaller than unity, especially in the case of inorganic aerosols.

Despite the short lifetime of OH in the troposphere, heterogeneous reactions involving OH are now recognized to be important due to their ability to initiate the oxidation of organic particulates, to react with inorganic aerosols, to modifying their physical and chemical properties, to release photochemically active halogen products to the gas phase, and to determine cloud chemistry to a significant extent. At an average OH concentration  $\sim 0.02$  ppt in the troposphere ( $\sim 10^6$  molecule  $\text{cm}^{-3}$ ), radical uptake becomes often a rate-determining step in an entire process of further physicochemical transformation of aerosol particles. However, atmospheric modeling of aerosol chemistry is to a large extent constrained by the very limited experimental kinetic data on radical uptake.

#### 1.4. Reaction Probabilities of OH on Aerosol Surfaces

Hanson *et al.* [1992] measured the reaction probabilities,  $\gamma$ , also known as *the uptake coefficient*, defined as the ratio of *the number of gas molecules reacting with the surface to the number of gas molecules colliding with the surface* [Brown, 1978; Kolb *et al.*, 1995; Molina *et al.*, 1996],

$$\gamma = \frac{\text{number of gas molecules reacting with the surface}}{\text{number of gas molecules colliding with the surface}} \quad (1.8)$$

using a wetted wall flow tube and the laser induced fluorescence (LIF) detection technique. The reported  $\gamma_{\text{OH}}$  on pure liquid water and 28% w/w sulfuric acid (H<sub>2</sub>SO<sub>4</sub>)

are 0.0035 at 275K and 0.08 (the lower limit) at 249K, respectively. The value at room temperature was reported at  $4.2 [\pm 2.8] \times 10^{-3}$  by Takami *et al.* [1998]. At the same time, water ice showed essentially higher reactivity to OH uptake. Cooper *et al.* [1996] determined  $\gamma_{\text{OH}}$  on water ice using their low-temperature flow tube coupled to a resonance fluorescence detector. The measured reaction probability on fresh ice was 0.1 while it became smaller with time, approaching a steady state value of 0.03.

**Table 1.2.** The measured OH reaction probabilities for various aerosol surfaces

Soot	0.88	Bertram <i>et al.</i> , 2001
Al <sub>2</sub> O <sub>3</sub>	0.20	Bertram <i>et al.</i> , 2001

The flow tube-electron paramagnetic resonance experiments carried out by Ivanov *et al.* [1996] measured  $\gamma_{\text{OH}}$  for dry NaCl and ammonium nitrate (NH<sub>4</sub>NO<sub>3</sub>) at  $3.2 \times 10^{-3}$  at 300 K and  $3.47 \times 10^{-3}$  at 297 K, respectively, showing a negative temperature dependence. Recently, our laboratory used a flow tube coupled with a chemical ionization mass spectrometer (CIMS) to investigate the reaction probabilities of OH on organic surfaces

(halocarbon wax, paraffin wax, methyl-terminated monolayer, stearic-palmitic acid, vinyl-terminated monolayer, pyrene, soot). The results indicate that the organic materials react efficiently with OH via heterogeneous H-abstraction reactions. In our laboratory  $\gamma_{\text{OH}} = 0.2$  for aluminum oxide ( $\text{Al}_2\text{O}_3$ ) was also determined [Bertram et al., 2001]. The OH reaction probabilities for the aerosol surfaces measured in the early studies are summarized in Table 1.2.

## 1.5. Tropospheric Aerosols

Aerosols in the troposphere are solid or liquid particles with particle sizes ranging from a few nanometers to tens of micrometers. They originate from natural and anthropogenic sources. Ocean wave actions and wind-blown mineral dust are the most important examples of natural sources, while combustion is an example of an anthropogenic source. Aerosol composition and concentrations are highly dependent on location. For example, urban areas normally contain more organic aerosols due to high anthropogenic activities compared to remote regions. Ocean-originated particles, such as sea salt aerosol, are rich in a coastal area, while mineral dust aerosols are typically abundant in a desert region. Water droplets forming fog or clouds are also important aerosol particles in the troposphere [Seinfeld and Pandis, 1998; Pandis *et al.*, 1990; Wieprecht *et al.*, 2005]. A study of OH heterogeneous reactions on tropospheric aerosol surfaces provides not only invaluable kinetics information to improve atmospheric models, but is also fundamental for our understanding of the heterogeneous chemistry of radicals.

### 1.5.1. Organic Aerosols

Carbonaceous aerosol particles consisting of both elemental carbon (EC) and organic carbon (OC) account for a major fraction of tropospheric aerosols, especially in urban areas. Field measurements have shown that 10-50% of particulate matter in the troposphere is carbonaceous [Larry *et al.*, 1999] with a global anthropogenic emission of 12-24 Tg yr<sup>-1</sup> [Cooke *et al.*, 1996; Penner *et al.*, 1998]. In particular, organics may comprise 15 – 60% of particulate matter < 10 µm in diameter (PM<sub>10</sub>) in urban areas, for example [Rau, 1989; Bertram *et al.*, 2001]. Primary OC is emitted directly into the atmosphere while secondary OC, also known as secondary organic aerosol (SOA), is formed by condensation of hydrocarbons through gas-phase reactions onto an existing aerosol surface [Pandis *et al.*, 1992; Seinfeld and Pandis, 1998]. Oxidation of hydrocarbons in the gas phase by OH, O<sub>3</sub>, or NO<sub>2</sub> followed by condensation on an aerosol surface is one of the examples of secondary OC formation as described in Figure 1.2. An amount of secondary OC also depends on the actinic flux and concentrations of pollutants. In most cases, primary OC dominates in the OC budget in the troposphere although the contribution of secondary OC increases during peak photochemical air pollution.

**Figure 1.2** Formation of secondary OC by oxidation of hydrocarbons

Soot is the most important atmospheric carbonaceous particle formed as a by-product of the incomplete combustion of organic fuels. Soot exhibits complex climate effects and participates in a variety of tropospheric chemical reactions. Consisting of both EC and OC, soot also contains hydrogen (up to 10%). The efficiency of soot formation significantly depends on the carbon/oxygen ratio in a fuel-air mixture. In the following example [Seinfeld and Pandis, 1998];

$C_s$  is the soot formed. When  $m = 2a$ , which is the sufficient oxygen condition, no soot is formed, while the amount of soot, that is  $(m - 2a)$ , increases under oxygen-poor conditions.

The elemental structure of soot is similar to that of graphite, which is stack of 2-Dimensional network planes. Then, these elements cluster with each other to form approximately 20-30 nm spherules which aggregate together into particles up to several microns in diameter. The structure and composition of soot particles are extremely complex and still not entirely understood.

### 1.5.2. Sea Salt

Sea salt particles are released to the troposphere by ocean wave actions followed by water evaporation. OH heterogeneous reactions on sea salt particles can play an important role in production of halogens, such as chlorine and bromine, responsible for further reactions in the troposphere and the stratosphere, including ozone destruction.

Sea salt is a complex mixture of different compounds. Although the composition of sea salt aerosols depends on the location of their origin, the major

components are sodium chloride (NaCl), magnesium chloride (MgCl<sub>2</sub>), and sodium sulfate (Na<sub>2</sub>SO<sub>4</sub>). The typical composition of a sea salt mixture is listed in Table 1.2 [Lin *et al.*, 1991].

**Table 1.3.** Composition of sea salt [Lin *et al.*, 1991]

Composition	Percent by Weight (%)	Density (g/L)
NaCl	58.490	24.530
MgCl <sub>2</sub> ·6H <sub>2</sub> O	26.460	5.200
Na <sub>2</sub> SO <sub>4</sub>	9.750	4.090
CaCl <sub>2</sub>	2.765	1.160
KCl	1.645	0.695
NaHCO <sub>3</sub>	0.477	0.201
KBr	0.238	0.101
H <sub>3</sub> BO <sub>3</sub>	0.071	0.027
SrCl <sub>2</sub> ·6H <sub>2</sub> O	0.095	0.025
NaF	0.007	0.003

Although the composition of sea salt is initially the same as that of sea water when it is emitted from the ocean, field observations report a chloride deficit in the sea salt particles showing low Cl/Na ratio as they are aged [Junge, 1956; Cicerone, 1981; Keene *et al.*, 1990; Mouri *et al.*, 1993; McInnes *et al.*, 1994]. It is suggested that heterogeneous reactions between gas phase pollutants and sea salt particles are responsible for the depletion of chlorine, as follows [Hemminger, 1999].

Besides gas phase pollutant, the O<sub>3</sub> and OH heterogeneous reactions on sea salt

particles have been studied and suggested as an additional chlorine deficit source [Oum *et al.*, 1998; Finlayson-Pitts, 2003]. However, the kinetics mechanisms for these reactions are still unknown.

### 1.5.3. Mineral Dust Particles

Mineral dust particles originate from very specific parts of the Earth's surface, mostly from desert regions, by wind actions [Prospero *et al.*, 2002]. Mineral dust particles are typically a mixture of various mineral compounds, such as silicon dioxide (silica, SiO<sub>2</sub>), aluminum oxide (alumina, Al<sub>2</sub>O<sub>3</sub>), and calcium carbonate (calcite, CaCO<sub>3</sub>). Due to their long lifetime, mineral dust particles can be transported at long distances and spread globally, affecting climate and the tropospheric chemistry as well as playing an important role in cloud physics and chemistry by acting as cloud condensation nuclei (CCN). In addition, mineral dust aerosols can affect the radiation balance in the atmosphere by reflecting, scattering, and absorbing the incident solar light [Prospero *et al.*, 2002; Laskin *et al.*, 2005; Vlasenko *et al.*, 2006]. Another important role of mineral dust particles is to provide reaction sites for uptake of atmospheric gaseous species that can be eventually involved the following redox reactions of catalytic destruction [Ross *et al.*, 1991; Matthijsen *et al.*, 1995; Dentener *et al.*, 1996]

Mineral dust particles are initially practically insoluble even though they are hydrophilic. However, as they are exposed to the gas phase environment in the troposphere, the aerosol particles become soluble by reacting with labile species, such

as, for example, nitric acid (HNO<sub>3</sub>). The following example shows conversion of initially insoluble calcium carbonate (CaCO<sub>3</sub>) particles to soluble calcium nitrate (Ca(NO<sub>3</sub>)<sub>2</sub>) upon HNO<sub>3</sub> uptake on the aerosol particles in the troposphere [Krueger *et al.*, 2003].

## 1.6. Heterogeneous Reactions under High Humidity Conditions

Little is known of OH heterogeneous chemistry under real tropospheric conditions where water vapor is one of the major components of the troposphere, reaching up to 4% by volume. Relative humidity (RH) is defined as the ratio of the partial pressure of water (P<sub>H<sub>2</sub>O</sub>) to its saturated vapor pressure (P<sup>0</sup><sub>H<sub>2</sub>O</sub>) at a given temperature.

$$RH(\%) = 100 \cdot \frac{P_{\text{H}_2\text{O}}}{P_{\text{H}_2\text{O}}^0} \quad (1.19)$$

Due to its relatively large dipole moment ( $1.83 \times 10^{-18}$  esu·cm) and the ability to form strong hydrogen bonds, water vapor can be easily adsorbed on the aerosol surfaces, such as salts and dust particles, with high surface tension [Hemminger, 1999]. For example, several studies showed that a water monolayer starts to appear on the NaCl (100) surface even at 35% of RH, which is significantly below the deliquescence point of RH = 75% [Peters *et al.*, 1997]. A similar value was reported by Hemminger [1999] who showed that the first monolayer of water was completed at 20% of RH, whereas multilayer water was efficiently formed above 31 % RH. Hemminger also showed that the adsorbed water enhanced the ionic mobility on a surface at extremely low RH = 2%.

This result implies that OH heterogeneous reactions on aerosol surfaces can be influenced by RH of a much wider range. Therefore, for the tropospheric chemistry it is important to know how the OH heterogeneous reactions change under wet conditions.

#### 1.6.1. Molecular water bonding to surfaces

Thiel *et al.* [1987] stated the following general features which describe the interaction of water with most surfaces. Since they are important and well described, four features were considered.

- (1) Water bonds through the oxygen atom to the surface. Hydrogen bonds with the surface ( $O-H\cdots S$  bonds, where  $S$  = surface) are rare. Similarly, water forms bonds to metal atoms in complexes and clusters via the oxygen atom [Nakamoto, 1970; Ferraro, 1971].*
- (2) Bonding is accompanied by net charge transfer to the surface. Therefore water acts as a Lewis base. Charge transfer to the surface manifests itself in a negative work function change upon adsorption.*
- (3) The internal bond angle, bond lengths, and vibrational frequencies of the molecules are only slightly perturbed from the gas phase values by the interaction with the surfaces.*
- (4) Formation of hydrogen-bonded clusters is common, even at very low coverages, because hydrogen bonding between two or more  $H_2O$  molecules is often energetically competitive with the molecule-substrate bond.*

#### 1.6.2. Technical problems in experiments with water vapor

Technical problems arise in experiments conducted at high water vapor pressure

conditions. Achieving a relative humidity of up to 50% requires a considerable flow of carrier gas that builds up relatively high pressure of 100-200 Torr inside a flow tube reactor. Such high pressure conditions significantly slow down the fast radical uptake rate which becomes already determined by diffusion of radicals to reactor walls [Rudich *et al.*, 1996; Zasyarkin *et al.*, 1997; Pöschl *et al.*, 1998]. Increasing the surface area available for reaction by using a set of sub-size tube array or a glass bead packing inside a flow tube enables simultaneously to maximize the rate of a heterogeneous reaction and minimize diffusion limitations.

The sensitivity of chemical ionization mass spectroscopy (CIMS) detection is also affected by high water vapor pressure. Water vapor reduces significantly the CIMS sensitivity to OH due to efficient formation of water complexes with the  $\text{SF}_6^-$  reagent ion, such as  $\text{SOF}_4^-(\text{H}_2\text{O})_m$ ,  $\text{F}(\text{HF})_2(\text{H}_2\text{O})_n$ , and  $\text{F}(\text{HF})_n$  where  $m$  and  $n$  are complex numbers [Wickramanayake, 1986; Arnold *et al.*, 2001]. Besides complex formation with  $\text{SF}_6^-$ , OH also efficiently forms water clusters that reduce considerably its detection limit [Salcedo *et al.*, 2004]. Although dilution with an additional flow of He helps partially to minimize the efficiency of water-complex formation [Arnold *et al.*, 2001], calibration of sensitivities at different RH, or compensation of this effect by monitoring the reference are still necessary under high RH conditions, which the latter is simpler than former to be performed.

### **1.7. Chemical Ionization Mass Spectrometry (CIMS)**

Compared to conventional electron impact (EI) ionization or laser induced ionization, CIMS provides much less destructive ionization of detected species [Hanson *et al.*, 1991; Villalta *et al.*, 1995; Seeley *et al.*, 1996; Lipson *et al.*, 1999]. For CIMS

detection, a parent ion (or reagent ion), such as  $\text{SF}_6^-$ ,  $\text{F}^-$ ,  $\text{O}_2^-$ , and  $\text{NO}_2^-$ , meets a gas-phase molecule of interest in a chemical ionization region (a CI region) where electron transfer enables detection via the following reaction:

where  $\text{X}^-$  is the parent ion and M is a gas-phase molecule of interest. A series of lenses focuses the ionized species into a quadrupole mass analyzer for detection. The ‘soft’ ionization, which is specific for CIMS, minimizes fragmentation of the molecules resulting in enhancement of sensitivity and simplicity of analysis.

## 1.8. Thesis Outline

The main objective of this thesis is to understand how OH uptake by surfaces of tropospheric interest depends on relative humidity. This also includes the investigation of the reaction mechanism of the heterogeneous interaction of OH with a NaCl surface under dry and wet conditions. The information obtained contributes to better understanding the OH heterogeneous chemistry under realistic tropospheric conditions, thereby providing experimental data essential for improving the accuracy of atmospheric models.

Chapter 2 describes in detail the experimental setup used in the present study. The setup consists of a flow tube system with a reference and a reactor coupled to a CIMS. In addition, details about the path of the OH radical from its generation to detection are delineated.

In chapter 3, the dependence of the OH reaction probabilities on relative humidity of 0 to 48% is described for various organic and inorganic surfaces. Organic

surfaces studied in this work are paraffin wax, pyrene, and methane soot that served as proxies for hydrophobic aerosols, and glutaric acid ( $\text{C}_3\text{H}_6(\text{CO}_2\text{H})_2$ ) that served as proxy for hydrophilic ones. Inorganic surfaces, such as sodium chloride ( $\text{NaCl}$ ), magnesium chloride ( $\text{MgCl}_2$ ), sodium sulfate ( $\text{Na}_2\text{SO}_4$ ), calcium chloride ( $\text{CaCl}_2$ ), potassium chloride ( $\text{KCl}$ ), and sea salt, are used as proxies for marine-originated sea salt aerosol, while silicon oxide and aluminum oxide are used to imitate mineral dust surfaces. A virtual tube approximation is proposed and successfully developed in the current study as a kinetics method employed to determine the OH reaction probability using a differential bead-packed flow tube.

Chapter 4 considers in detail the reaction mechanism of molecular chlorine formation in the heterogeneous OH + NaCl reaction. The obtained experimental data confirm that molecular chlorine detected in the gas-phase is a major product of the OH heterogeneous reaction with a NaCl surface. In addition, XPS experiments are carried out to study chemical composition transformation of the salt surface exposed to OH. The dependence of the efficiency of chlorine production on RH is also described.

The conclusion section (Chapter 5) summarizes the results and intermediate conclusions made in the previous chapters.

After the conclusion section (Chapter 6), recommendations for future studies are suggested: studies of heterogeneous  $\text{HO}_2$  reactions on surfaces of tropospheric interest under humid conditions are also of atmospheric importance and would considerably complement the results of the current studies.

## **Chapter 2**

# **Experimental**

The experimental setup used in the present studies consists of parallel reactor tubes connected to a chemical ionization mass spectrometer. OH radicals are generated then exposed to surfaces of interest under dry and wet conditions in a flow tube system. Products of the heterogeneous reactions and OH radicals which have survived from heterogeneous losses are ionized for CIMS detection.

## 2.1. The Flow Tube System

The parallel flow tube design used in the present work is shown in detail in Figure 2.1. The flow tubes and the entire line of flow pathway made of borosilicate glass were completely coated with halocarbon wax (Halocarbon Inc., 600 series and 1500 series), to minimize unwanted heterogeneous reactions due to its low reactivity with OH,  $\gamma_{\text{OH}} = 6 \times 10^{-4}$  [Bertram *et al.*, 2001]. The series numbers represent the average molecular weight of halocarbon wax wherein the higher molecular weight corresponds to greater inertness. No significant difference between 600 series and 1500 series halocarbon wax was observed under the experimental conditions employed in this work. Therefore, only 600 series halocarbon was used for convenience since it allowed for even coating at lower temperatures ( $\sim 200^\circ\text{C}$ ).

**Figure 2.1** The flow tube system used in present work.

Gas flow rates were monitored with electronic mass flow meters (Millipore, Tylan). Since each flow meter was factory-calibrated by a specific gas flow, such as nitrogen or helium, a conversion factor is necessary when other gases are used in the experiments due to the different gas expansion. The conversion factor of He for N<sub>2</sub> calibrated mass flow meter is 1.45 [MKS Instruments].

For gas mixtures, gas correction factors (GCF) defined as following are necessary to determine the actual flow rate:

$$GCF = 0.3106 \frac{\sum a_i s_i}{\sum a_i d_i c_{pi}} \quad (2.1)$$

where,  $a_i$  is the fractional flow of gas  $i$  (dimensionless),  $s_i$  is the molecular structure factor for gas  $i$  (dimensionless),  $d_i$  is the standard density for gas  $i$  (g/L), and  $c_{pi}$  is the specific heat capacity for gas  $i$  (cal/g °C). The molecular structure factors are 1.030 for monoatomic gases, 1.000 for diatomic gases, 0.941 for triatomic gases, and 0.880 for polyatomic gases [MKS Instruments].

For the diluted gas mixtures used in this work, which are 1% by volume (v/v) of NO<sub>2</sub> in He and 5% v/v O<sub>2</sub> in He, GCF were applied for He only since the contributions of NO<sub>2</sub> and O<sub>2</sub> were negligible. In the case of H<sub>2</sub>/He and SF<sub>6</sub>/N<sub>2</sub>, the flow rates for the individual gases (H<sub>2</sub>, He, SF<sub>6</sub>, and N<sub>2</sub>) were monitored by individual mass flow meters before mixing.

All glass and metal tubes in the flow system were connected through stainless steel Ultra-Torr vacuum fittings (Swagelok). Two direct type mechanical pumps (E2M-12 and E2M-80, BOC Edwards) maintained the base pressure of the flow system at 0.1 Torr, monitored by a pressure transducer (Baratron, MKS Instruments).

A decrease in temperature was expected inside the reduced pressure of flow

tube system due to gas expansion. The direct measurement of temperature inside the flow tube at 100 Torr was approximately one centigrade degree lower than the laboratory temperature.

## 2.2. OH Production and Calibration

Two different OH sources were used for OH production. The first source employed the following fast reaction ( $k_{2,2} = 1.3 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ ) [DeMore *et al.*, 1997] in an excess of H over NO<sub>2</sub>:

A molecular hydrogen flow was diluted by helium (Airgas, UHP), then discharged inside a Beenaker microwave discharge cavity [Fehsenfeld *et al.*, 1965] operating at 30W to produce hydrogen atoms ( $\sim 5 \times 10^{12} \text{ molecule cm}^{-3}$ ) available to react with NO<sub>2</sub> ( $\sim 1 \times 10^{12} \text{ molecule cm}^{-3}$ , Matheson Tri Gas, 99.5%) in the 0.400-cm i.d. tube. To prevent OH loss via self-recombination, the flow contained OH ( $\sim 10^{11} \text{ molecule cm}^{-3}$ ) was expanded in a mixing tube (0.950-cm i.d.) and additionally diluted with nitrogen (N<sub>2</sub>, PraxAir), the main carrier gas.

The second OH source used for a NO<sub>x</sub>-free conditions follows a sequence of two reactions ( $k_{2,3} = 1.9 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 100 Torr [DeMore *et al.*, 1997],  $k_{2,4} = 7.2 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Atkinson *et al.*, 2001]) in excess of H radicals:

Initially produced HO<sub>2</sub> reacts promptly with the excess H radicals to generate OH. Since Reaction 2.4 is relatively fast, production of HO<sub>2</sub> was negligible (HO<sub>2</sub>/OH  $\sim 1 \times 10^{-2}$ ).

Reaction 2.2 was also used to determine the CIMS sensitivity to OH. For calibration, the dependence of an OH signal was monitored upon introducing known amounts of NO<sub>2</sub>, where the NO<sub>2</sub> mixing ratio in a prepared bulb was first verified by UV/Vis spectrometry. The same OH sensitivity was also applied to either production methods.

**Figure 2.2** The OH intensity dependence on NO<sub>2</sub> concentration ([NO<sub>2</sub>]). The OH intensity increases linearly in region I, finally reaching a plateau as NO<sub>2</sub> is consumed and secondary reaction take over.

Figure 2.2 shows how OH intensity depends on NO<sub>2</sub> concentrations ([NO<sub>2</sub>]). At low [NO<sub>2</sub>], the OH intensity increased linearly as [NO<sub>2</sub>] increased (region I) in accordance with Reaction 2.2. However, at high [NO<sub>2</sub>], secondary chemistry of OH becomes important, significantly lowering the OH yield by the following reactions (region II):

where the termolecular rate constants ( $k' = k[\text{M}]$ ) are  $1.6 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  and  $3.8 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 100 Torr, respectively. Therefore, the OH calibration was determined based on the experimental data taken from region I. Figure 2.3 shows that typical sensitivities of OH and NO<sub>2</sub> intensities were found to be  $4.2 [\pm 0.3] \times 10^7 \text{ molecule cm}^{-3} \text{ cps}^{-1}$  and  $1.07 [\pm 0.02] \times 10^9 \text{ molecule cm}^{-3} \text{ cps}^{-1}$ , respectively. The detection limit for OH was found at  $\sim 10^{10} \text{ molecule cm}^{-3}$  at 100 Torr.

Since the OH intensity used in the flow tube was typically 20 keps (kilocounts per second) under dry conditions, the concentration of OH ( $[\text{OH}]$ ) in the flow tube was approximately  $8 \times 10^{11} \text{ molecule cm}^{-3}$ . However, CIMS sensitivity decreased significantly under wet conditions due to water interference on the chemical ionization reactions as described in Chapter 1. For example, the OH sensitivity at 6% of RH was one order of magnitude smaller than that under dry conditions.

Measured OH reaction probabilities were independent of the OH sources used. However, it should be noted that NO<sub>x</sub>-free OH source (Reactions 2.3 and 2.4) typically resulted in a relatively higher OH yield, and therefore, was primarily used in our experiments to study the effects of relative humidity on OH uptake by surfaces of tropospheric importance (see Chapter 3). However, interference by secondary reactions between H, O<sub>2</sub>, and HO<sub>2</sub> could be avoided by using the first source (Reaction 2.2) for the product study (see Chapter 4).

**Figure 2.3** OH (a) and NO<sub>2</sub> (b) calibrations

### 2.3. Water Bubbler

Relative humidity of up to ~50% was produced in the flow tube system by

means of a water bubbler. An additional N<sub>2</sub> flow passed through a porous disk in a water bubbler (70 cm o.d.) to carry saturated water vapor as described in Figure 2.1 and Figure 2.4. The water vapor contained flow then was introduced to a mixing tube where it was mixed with a main carrier flow.

**Figure 2.4** A schematic of the water bubbler

Glass wool was placed in the outlet of the water bubbler to refine the flow from water droplets coming from bubbling action at the interface. A total pressure of 100 Torr inside the flow tube was maintained by adjusting the main carrier gas flow. To estimate the partial pressure of water vapor, the same N<sub>2</sub> flow bypassed a water bubbler and the difference in pressures produced by the wet and dry N<sub>2</sub> flows was used based on the Dalton's law of partial pressures:

$$P_{H_2O} = P_{total} - P_{bypass} \quad (2.7)$$

Then relative humidity was determined according to Equation 1.19 using the partial pressure of water and the saturated vapor pressure of water at given temperature as listed in Table 2.1 [Haar *et al.*, 1984; Lide *et al.*, 2007].

**Table 2.1** Saturated water vapor pressure

Temperature °C	Vapor Pressure Torr	Temperature °C	Vapor Pressure Torr
18	15.5	22	19.8
19	16.5	23	21.1
20	17.5	24	22.4
21	18.7	25	23.8

## 2.4. Parallel Reactor Tubes

Two identical reactor tubes (0.950-cm i.d.) were placed downstream of the OH production region and mixing tube. The each reactor was filled with 60 borosilicate glass beads (3 mm o. d., Chemglass). To remove any organic and inorganic deposition, the beads were cleaned with sulfuric, nitric, and hydrofluoric (HF) acids prior to running an experiment. Exposure to HF for 10 seconds was sufficient to remove residual organic/inorganic material. The efficient reaction between HF and  $\text{SiO}_2$  changed the roughness of the glass beads surface as can be seen in Figure 2.5.

**Figure 2.5** Optical microscopic images of raw borosilicate glass bead surface (a) and HF treated surface (b).

Nevertheless, testing both the untreated and HF-treated glass beads showed no difference in OH uptake, indicating that the pre-treatment did not affect reactivity measurements.

In our study, the glass beads were coated with the organic or inorganic materials and placed in the reactor tube, while beads in a reference tube were coated with halocarbon wax. Detailed description of the surface preparation is given in Section 2.2. It should be noted that the beads-packing caused a gas-dynamic resistance to a flow which led to a pressure gradient of 6-9 Torr. This pressure drop was neglected and the measured flow tube pressure (100 Torr) upstream of the beads was assumed to be accurate within  $\pm 5\%$  error.

Using two stop valves, the total flow may be switched between the reactor tube and the reference tube to compare OH uptake on a reactive and inert surfaces. A parallel reactor tubes is particularly useful for the following reasons:

- (1) Due to the beads packing design, the use of a movable injector that normally is employed as a movable radical source in kinetic studies to vary reaction time is not applicable in the present work and so the referencing OH heterogeneous loss on a reactive surface to that on an inert material seems to be the most appropriate way to determine the reaction probability,  $\gamma_{\text{OH}}$ . The detailed description of the routine used to determine  $\gamma_{\text{OH}}$  in a flow tube filled with beads is shown in Section 3.3.3.4. It should be noted that in our kinetics method, for a reference surface, such as halocarbon wax, a value of  $\gamma_{\text{OH}}$  should be known and measured accurately which is the case for halocarbon wax 600 series; the value of  $6 \times 10^{-4}$  was measured previously in many studies (see, for example, Bertram *et al.*, 2001).

(2) In fact, the reference technique does not require knowing the dependence of the CIMS sensitivity to OH on RH because of its subtraction when two OH signals are compared (see Chapter 3). The same is applied for by-products produced in the reaction of OH with flow tube walls coated with halocarbon wax: if Cl-contained species is formed upon the OH exposure of flow tube walls, it will be subtracted when both OH signals after reacting with reactive and inert surfaces are compared (see Chapter 4).

## 2.5. Flow Rates and Velocities

The two gas flows of N<sub>2</sub> and He formed a carrier gas flow in a flow tube with flow rates of 0.8 SLPM (standard liters per minute) and 1.75 SLPM, respectively, for a total flow rate of 2.55 SLPM. A linear transport velocity under the total flow (in cm s<sup>-1</sup>) was determined as follows:

$$v = \frac{w}{s \cdot p} \cdot \frac{T}{273} \cdot \frac{1000}{60} \quad (2.8)$$

where  $w$  is the total flow rate in L/min,  $T$  is the gas temperature in a flow tube in K,  $s$  is the cross section of a flow tube in cm<sup>2</sup>,  $p$  is the pressure in a differential flow tube in Torr, and 1000 and 60 are the conversion factors of L to cm<sup>3</sup> and of minutes to seconds, respectively. Since the inner diameter of the reactor was 0.95 cm,  $v$  was calculated to be 480 cm/s.

Under given conditions, the Reynolds number as defined in Equation 2.9 was 341, corresponding to the laminar flow ( $Re \ll 2300$ )

$$Re = \frac{2rv\rho}{\eta} \quad (2.9)$$

where  $r$  is the radius of a flow tube,  $\rho$  is the gas density, and  $\eta$  is the gas viscosity.

As seen from Equations 2.8 and 2.9, flow velocity and the Reynolds number depend strongly on a radius of the flow tube. When the equations are applied for the beads-packing design, these equations produce different values of the parameters (see Section 3.3.3).

## **2.6. Pressure Reduction**

At downstream of differential flow tube a total flux was then differentially pumped out so that only a small fraction (~1%) of the total flow was introduced via a skimmer of 1- mm I.D. to the chemical ionization region for further detection of OH; the rest of a total flow was pumped out by a mechanical pump (E2M-12, BOC Edwards). The differential pumping helped to reduce the pressure in the chemical ionization region and in addition to remove water vapors to minimize water-cluster formation influencing OH detection. Our experiments showed that the enhancement in OH sensitivity as a result of pumping ranged from 50% (at 4% RH) to a factor of 10 (at 48% RH).

For the product study under dry and low RH conditions (see Chapter 4), differential pumping was shut off to maintain high sensitivity to the gas-phase products, especially chlorine-containing species, enabling detection of the gas phase species without additional loss.

## **2.7. Detection Method**

In the present studies, OH and gas-phase products were detected using chemical ionization mass spectrometry (CIMS). The chemical ionization mass spectrometer consists of a custom-built chemical ionization region (CI region) coupled to a

commercial quadrupole mass spectrometer (Extrel CMS) used for mass selection and electron multiplier (Channeltron) for ion detection. The schematic of the CIMS used in this work is shown in Figure 2.6.

**Figure 2.6** The schematic of the CIMS setup

### 2.7.1. CI region

To enable their detection, OH radicals and gas phase reaction products were ionized by charge transfer reactions with sulfur hexafluoride ( $\text{SF}_6^-$ ) as the parent ion. To produce  $\text{SF}_6^-$  ions, a small flow of  $\text{SF}_6$  (Matheson Tri Gas, 99.99%) was initially diluted with  $\text{N}_2$  to 0.1% by volume and passed through a radioactive polonium source (NRD,  $^{210}\text{Po}$ ). The  $\text{SF}_6^-/\text{N}_2$  flow (1.5 SLPM) was introduced to a stainless steel tube of 1-inch o.d. coated with halocarbon wax. In the CI region,  $\text{SF}_6^-$  was used to ionize the following species:

with the rate constants,  $k_{2.10} = 2 \times 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Lovejoy *et al.*, 1990],  $k_{2.11} = 1.4 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Huey *et al.*, 1995],  $k_{2.12} = 6.1 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Streit, 1982], and  $k_{2.13} = 4.2 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Streit, 1982]. A negative potential of -10 V was applied to the CI region to prevent the loss of negative ions on a stainless steel surface, and to further accelerate the ions for detection.

As described in Chapter 1, water vapor interacts with  $\text{SF}_6^-$  by forming water complexes, such as  $\text{SOF}_4^-(\text{H}_2\text{O})_m$ ,  $\text{F}^-(\text{HF})_2(\text{H}_2\text{O})_n$ , and  $\text{F}^-(\text{HF})_n$  [Wickramanayake, 1986, Arnold *et al.*, 2001]. This loss of the parent ions would result in the significant lowering CIMS sensitivities to the detected species including OH. Moreover, in the CI region, water vapor readily forms water clusters with  $\text{OH}^-$ , such as  $\text{OH}^-(\text{H}_2\text{O})_n$ , also reducing the OH sensitivity [Salcedo *et al.*, 2004]. The distribution of  $\text{F}^-(\text{HF})_n$  and  $\text{SF}_4\text{O}^-$  (a) and  $\text{OH}^-(\text{H}_2\text{O})_n$  (b) at various RH is shown in Figure 2.7.

To increase the CIMS sensitivity under wet conditions, an additional He flow of 2 SLPM was added to reduce cluster formation [Arnold *et al.*, 2001]. Although the He-buffer flow increased a total pressure in the CI region from 1.9 Torr to 10 Torr resulting in lowering OH sensitivity under dry condition as seen in Figure 2.8, however, the CIMS sensitivity increased significantly under wet conditions with He-buffer flow. Our experiments showed that for example, the OH intensity increased by factor of 17 with the He buffer flow at 38% RH, while it was barely observed without He buffer flow.

**Figure 2.7** Distributions of  $\text{F}^-(\text{HF})_n$  and  $\text{SF}_4\text{O}^-$  (a), and  $\text{OH}^-(\text{H}_2\text{O})_n$  (b) in the presence of RH. There is no correlation in the arbitrary units between (a) and (b).

**Figure 2.8** The OH intensity dependence on RH with (■) and without (○) He buffer flow

### 2.7.2. Mass Spectrometer

Only a small amount of a flow containing both neutral and ionized species was introduced to the mass spectrometer (MS) via a 100- $\mu\text{m}$  pinhole skimmer biased at -5 V. Ions were focused into the MS through a negatively charged metal ring (high pressure lens) placed immediately after the CI region. In contrast, most amount of flow was pumped out by a mechanical pump (E2M-80, BOC Edwards) to maintain the low pressure of the MS, otherwise, the MS would be damaged.

An array of four ion lenses applied with different potentials, located just behind the pinhole and inside the MS chamber, was used to further focus ions into the quadrupole. A potential of approximately 3 kV impressed across the length of a continuous-dynode type electron multiplier (Channeltron 4870E, Burle Electro-Optics) induced a cascade of electrons by the strike of the analyzed ions with approximately  $10^8$

of gain. The resulting signal was pre-amplified (MTS-100, Advanced Research Instruments Corp.) then digitized and processed with a Merlin Automation System (Extrel).

Two turbo molecular pumps (360CSV, Leybold; STP-400, Seiko-Seiki) each with backing pumps (E2M-12, BOC Edwards; SD-450, Varian Inc.) were used to maintain the MS pressure below  $8 \times 10^{-6}$  Torr.

## **Chapter 3**

# **The Effects of Relative Humidity on OH Uptake by Surfaces of Tropospheric Importance**

### 3. 1. Introduction

Due to its relatively large dipole moment and capability for strong hydrogen bonding, a water molecule may be taken up efficiently by surfaces with high surface tension [Liu *et al.*, 1996; Ball, 1999; Aloisio *et al.*, 2000; Staikova *et al.*, 2001; Mantz *et al.*, 2002]. Adsorbed water can efficiently affect, either inhibiting or enhancing, OH uptake through modifying the nature of surface active sites, which can in turn lead to different reaction mechanisms than under dry conditions. For instance, exposing OH to carbonaceous surfaces results in increased hydrophilicity with a greater water adsorption capacity [Bertram *et al.*, 2001, Zuberi *et al.*, 2005]]. A water adlayer can block active sites from further reaction [Remorrov *et al.*, 2002], or may enhance the chemical reactivity of active sites by increasing the coordination number and causing partial dissociation in the aqueous environment. For inorganic surfaces, adsorbed water can notably enhance the surface ionic mobility, thereby affecting ionic concentrations [Hemming, 1999], as well as pH of an aerosol surface. All of these effects are expected to influence OH uptake, and in particular, the reaction mechanism. For example, segregation of halide ions observed at a surface of sea salt aerosol particles under wet conditions was found to be likely a key step in formation of gas-phase halogen-containing products [Dement'ev *et al.*, 2004].

To date, very little is known regarding the mechanism of OH uptake by aerosol surfaces under wet conditions. Only one study on OH uptake by organic surfaces reports direct measurement of the reaction probability, under conditions of low pressure and relative humidity (RH) < 1% [Molina *et al.*, 2004]. Results of this study showed that the OH reaction probability is independent of the presence of water vapor for initially hydrophobic organic surfaces, such as aliphatic, aromatic, and soot. OH

uptake measurements for deliquesced sea salt and its individual components have been performed at  $RH \geq 80\%$  [Oum *et al.*, 1998; Knipping *et al.*, 2002; Laskin *et al.*, 2006]. Results of these indirect measurements indicated noticeable enhancement in the OH uptake rate on the surfaces exposed to water vapor.

In this chapter, a new complementary approach has been developed and used to explore experimentally the RH effect on OH uptake by various organic and inorganic surfaces relevant to the troposphere. The new approach is based on the flow tube reactor system described previously (see Chapter 2), a virtual flow tube approximation and surface dilution technique that enables measurements of radical uptake with the initial probability near unity at high pressure and relative humidity.

## 3. 2. Experimental

The details of the experimental setup including the flow tube system equipped with CIMS were described in Chapter 2.

### 3.2.1. Radical Production

Among the two methods for OH production, the ‘H + O<sub>2</sub> + M’ scheme (Reaction 2.3 and 2.4) was employed due to its high radical yield.

where the rate constants are  $k_{2,3} = 1.9 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 100 Torr [DeMore *et al.*, 1997] and  $k_{2,4} = 7.2 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Atkinson *et al.*, 2001]. The sensitivity of OH was  $4.2 [\pm 0.3] \times 10^7 \text{ molecule cm}^{-3} \text{ cps}^{-1}$  under dry conditions, while it

became smaller under wet conditions [Section 2.2].

### 3.2.2. Experimental Procedure

The system was normally allowed to stabilize under flow conditions for thirty minutes before acquiring data on OH concentration. The OH peak was integrated in each mass spectrum to determine a peak area, and then average  $\sim 200$  points to obtain a median and a standard deviation. Once the signal intensity of OH was acquired upon exposing the OH to a material surface of interest, the gas flow was switched to a reference flow tube to acquire the reference signal for the comparison of which comprised a single experiment. A set of three to four experiments at each RH was repeated to confirm reproducibility of the data as well as for statistical considerations.

The RH was increased incrementally from 0% to 48%, followed by an extra measurement taken at 0% RH to evaluate possible aging of surface by OH-oxidation within the course of the experiments.

A main flow in the flow system was the mixture of  $N_2$ , He, and water vapor with the flow rates 1.75 SLPM, 0.80 SLPM, and 0 SLPM, respectively, under dry conditions, and 1.45 SLPM, 0.80 SLPM, and 0.3 SLPM, respectively, at RH = 48%. Experiments were performed at room temperature with  $\pm 1^\circ C$  tolerance.

### 3.2.3. Surface Preparation

The surfaces of the glass beads were coated with the organic and inorganic materials of interest listed below.

- (1) Reference : Halocarbon wax of a 600 series;
- (2) Organic materials : paraffin wax, pyrene( $C_{16}H_{10}$ ), glutaric acid ( $C_5H_8O_4$ ),

methane soot;

(3) Inorganic materials:

(a) Sea salt compounds : NaCl, MgCl<sub>2</sub>, Na<sub>2</sub>SO<sub>4</sub>, CaCl<sub>2</sub>, KCl, Sea salt;

(b) Mineral dust compounds : SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>;

For the reference coating, we carefully controlled the temperature with a heat gun in order to melt halocarbon wax without its decomposition followed by adding it into a beaker with glass beads. The glass beads were vigorously stirred to ensure a thin and smooth coating as halocarbon wax solidified on the surface of the beads at room temperature. The coated surface was observed using an optical microscope (Zeiss Axioskop 20 microscope equipped with 50 x objectives). As shown in Figure 3.1 (a), the surface was evenly and completely covered.

The same method was applied to prepare paraffin wax (J.T. Baker), pyrene (99.5%, Sigma-Aldrich), and glutaric acid (99%, Sigma-Aldrich) coatings. The optical microscopic image shows that paraffin wax surface (Figure 3.1 (b)) was rougher than the halocarbon wax surface. However, it was shown that the difference in the surface roughness contributes negligibly to OH uptake (See Section 2.4). The pyrene surface shown in Figure 3.1 (c) was prepared from a mixture of halocarbon wax and pyrene in order to lower surface reactivity towards OH uptake (See Section 3.3.3.3).

**Figure 3.1.** Optical microscopic images of halocarbon wax (a), paraffin wax (b), pyrene (c), and glutaric acid (d) coatings.

In other cases, NaCl for example, the surface coatings were prepared in the following way for homogeneous thin coating on the surface of a spherical shape. First, halocarbon wax was pre-coated on the glass beads as described above. Then, the pre-coated beads with the fine powder of materials in a Petri dish were shaken vigorously to coat the aerosol powder on the sticky surface. The coverage of material of interest was controlled by adding different amount of powder to the Petri dish.

A methane-soot surface was prepared using the above method by depositing soot collected from a methane-air flame produced with a standard torch. Figure 3.2 shows the optical microscopic image of methane soot coating on the halocarbon waxed beads.

**Figure 3.2.** Optical microscopic image of methane soot. The soot was partially coated on the halocarbon wax pre-coated surfaces.

The aerosol materials in this work were NaCl (Mallinckrodt, 99.9%), MgCl<sub>2</sub> (Sigma-Aldrich, 99.5%), Na<sub>2</sub>SO<sub>4</sub> (Sigma-Aldrich, ≥99.0%), KCl (Fisher Scientific, ACS grade), CaCl<sub>2</sub> (Mallinckrodt, 99%), Sea Salt (Sigma-Aldrich), SiO<sub>2</sub> (Sigma-Aldrich, 99.6%), and Al<sub>2</sub>O<sub>3</sub> (Sigma-Aldrich, 99.9%). In addition, two mixtures were prepared: One was, so called, ‘synthetic sea salt’ which consisted of the same components in the same ratio as real sea salt. In the other mixture, so called, ‘synthetic sea salt without MgCl<sub>2</sub>’, only MgCl<sub>2</sub> was removed from synthetic sea salt. The prepared aerosol surfaces were dried for overnight under vacuum (< 0.1 Torr) after being packed into the reactor. This process is required to evaporate water vapors adsorbed on the coatings during the surface preparation [Peters *et al.*, 1997].

Figure 3.3 shows the optical microscopic images for NaCl, Na<sub>2</sub>SO<sub>4</sub>, KCl, and sea salt, which were partially covered for lowering reactivity towards OH heterogeneous reaction (See Section 3.3.3.3 for details). Water absorption caused the inorganic crystals to appear more round since the images were taken under atmospheric conditions (RH = 50% - 70%). Images for MgCl<sub>2</sub> and CaCl<sub>2</sub> surfaces were unavailable to be taken within the certain time frame due to their extremely high hygroscopic properties.

**Figure 3.3.** Optical microscopic images of NaCl (a), Na<sub>2</sub>SO<sub>4</sub> (b), KCl (c), and Sea Salt (d). The inorganic aerosol surfaces were partially coated on the halocarbon wax pre-coated surfaces.

**Figure 3.4.** Optical microscopic images of synthetic sea salt (a) and synthetic sea salt without MgCl<sub>2</sub> (b). Some crystals were out of focus.

**Figure 3.5.** Optical microscopic images of  $\text{SiO}_2$  (Silica) (a) and  $\text{Al}_2\text{O}_3$  (Alumina) (b). Alumina was partially coated on the halocarbon wax pre-coated surfaces.

There was no significant difference in the appearances of the synthetic sea salt and the synthetic sea salt without  $\text{MgCl}_2$  as seen in Figure 3.4. Figure 3.5 shows the optical microscopic images of  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$ .

Although the images shows increases in roughness caused from powder coatings, it is assumed that there is no significant effect from roughness changes in the same manner as paraffin wax coating discussed above.

#### 3.2.4. Theoretical Method

To characterize  $\text{OH}-(\text{H}_2\text{O})_n$  and  $\text{OH}^--(\text{H}_2\text{O})_n$  complexes, *ab initio* calculations were performed to obtain the global minima of these complexes. Geometries of the local minima of the complexes were optimized at the hybrid density functional B3LYP level of theory using a 6-31G(d,p) basis set. The energies for the optimized geometries of the complexes corrected by the zero-point energy (ZPE) were calculated using the same method and basis set. All calculations were carried out using GAUSSIAN 03 [Frisch et. al., 2003].

### 3. 3. Results and Discussion

#### 3. 3. 1. Reaction Probability, $\gamma$

For first-order loss kinetics, the observed rate constant ( $k_{obs}$ ) is determined by the following equation:

$$-\ln \frac{[OH]_t}{[OH]_0} = k_{obs} t \quad (3.1)$$

where  $t$  is the reaction time, and  $[OH]_0$  and  $[OH]_t$  are the concentrations of OH initially and at time  $t$ , respectively. Since the concentration is proportional to the intensity of the detection signal, Equation 3.1 can be rewritten in the following way:

$$-\ln \frac{I'_{OH}}{I^0_{OH}} = k_{obs} t \quad (3.2)$$

where  $I^0_{OH}$  and  $I'_{OH}$  are the signal intensities of OH initially and at time  $t$ , respectively.

In a cylindrical flow tube, the additivity of kinetic resistances allows determination of the chemical kinetics rate constant ( $k_{kin}$ ) from the observed rate constant of heterogeneous loss [Semenov, 1943; Brown, 1978; Zasytkin *et al.*, 1997; Bertram *et al.*, 2001]:

$$\frac{1}{k_{obs}} = \frac{1}{k_{kin}} + \frac{1}{k_{diff}} \quad (3.3)$$

$$k_{kin} = \frac{\gamma \cdot c_{avg}}{(2 - \gamma) \cdot r} \quad (3.4)$$

$$k_{diff} = \frac{3.66 D_c}{r^2 P} \quad (3.5)$$

where  $k_{diff}$  is the diffusion-controlled reaction rate constant ( $s^{-1}$ ),  $r$  is the reactor radius (cm),  $D_c$  is the diffusion coefficient of the reactant in the carrier gas ( $cm^2 s^{-1}$  Torr),  $P$  is the pressure (Torr), and  $c_{avg} = 60,197$  cm  $s^{-1}$  is the mean thermal velocity of OH at 293

K. Therefore the reaction probability,  $\gamma$ , is determined as follows:

$$\gamma = \frac{2rk_{kin}}{c_{avg} + rk_{kin}} \quad (3.6)$$

In the case of a carrier gas consisting of a mixture of different gases,  $D_c$  is determined by the combination rule for the diffusion coefficients of individual gases ( $D_{OH-i}$ ) with a mixing ratio ( $\alpha_i$ ) according to the Blanc's law [Blanc, 1908; Fairbanks *et al.*, 1950; Hanson *et al.*, 1992]:

$$D_c^{-1} = \sum_i \alpha_i \cdot D_{OH-i}^{-1} \quad (3.7)$$

The OH diffusion coefficients in N<sub>2</sub> and He ( $D_{OH-N_2}$  and  $D_{OH-He}$ ) were reported at  $163 \pm 20 \text{ cm}^2 \text{ Torr s}^{-1}$  and  $665 \pm 35 \text{ cm}^2 \text{ Torr s}^{-1}$ , respectively [Bertram *et al.*, 2001; Ivanov *et al.*, 2007]. In our studies, contribution of water vapor to net OH diffusion was assumed to be negligible since the OH diffusion coefficient in H<sub>2</sub>O ( $D_{OH-H_2O} = 171 \text{ cm}^2 \text{ Torr s}^{-1}$  at 296 K) [Hanson *et al.*, 1992; Ivanov *et al.*, 2007] is very close to that in N<sub>2</sub>. Moreover, the N<sub>2</sub> was the major gas in the flow even under high relative humidity. As shown in Appendix 3-I, for example, 12 Torr of water vapor corresponding to 50% of RH contributes only 1% to the net OH diffusion coefficient under typical experimental conditions.

### 3. 3. 2. The Relative Intensity of OH, $R_{surface}$

In kinetics studies, a movable injector is employed to vary a reaction time of heterogeneous reaction by changing the exposed fraction of a wall surface coated with material of interest to a reactive gas-phase species as it is schematically shown in Figure 3.6.

**Figure 3.6.** The schematic of a movable injector employed in kinetic studies of heterogeneous reactions. Gas-phase species of interest are effused from the end of a movable injector and react on the wall coated with material of interest. Variable positions of the movable injector change the fraction of a wall surface corresponding to different exposed lengths ( $L_1$  and  $L_2$ ) or different reaction times ( $t_1$  and  $t_2$ ).

However, use of a bead-packing reactor tube prohibits employment of a movable injector in the present work. Instead, two OH signals ( $I_{surface}^{OH}$  and  $I_{reference}^{OH}$ ) corresponding to the OH concentrations measured after exposure to the surface of interest and the reference (halocarbon wax) ( $[OH]_{reaction}$  and  $[OH]_{reference}$ , respectively) are compared. The *relative intensity of OH for the heterogeneous reaction on the surface of interest*,  $R_{OH}$ , is defined in the present work as the ratio of OH signals measured when a OH-containing flow switched from a reaction flow tube to a reference tube:

$$R_{OH} = \frac{[OH]_{surface}}{[OH]_{reference}} = \frac{I_{surface}^{OH}}{I_{reference}^{OH}} \quad (3.8)$$

Since each OH concentration is described in Equation 3.1,  $R_{OH}$  relates to the observed rate constants for each material as follows (See Appendix 3-II):

$$R_{OH} = \exp[-(k_{obs}^{surface} - k_{obs}^{reference}) \cdot t] \quad (3.9)$$

Therefore,  $R_{OH}$  can be estimated based the known value of the OH reaction probabilities for a surface material and the halocarbon wax ( $\gamma_{OH}^{\text{Halocarbon wax}} = 6 \times 10^{-4}$  [Bertram *et. al.*, 2001]) using Equations 3.8 and 3.9, and vice versa, any unknown OH reaction probability can be determined if  $R_{OH}$  is known.

To our knowledge, there is no theoretical consideration of heterogeneous radical loss in a flow tube packed with beads. In order to estimate  $k_{het}$  and  $t$  in a flow tube used in the present work, we simplified the reactor design by approximating the space between beads with a virtual cylindrical flow tube encompassing the same volume, with a wall surface area equal to the surface area of the beads

### 3.3.3. The Virtual Cylindrical Reactor (VCR) Approximation

The flow tubes used in the present study were packed with beads for two reasons: to increase a surface area for the heterogeneous reaction and to shorten the time necessary for OH diffusion to the surface. In the virtual cylindrical reactor (VCR) approximation, a flow tube packed with beads is virtually replaced for simplicity with a cylindrical reactor of radius,  $r_v$ , and length,  $l_v$ , chosen to correspond with the surface area of beads,  $S$ , and volume of space between the beads,  $V$ . Geometric parameters of such a virtual cylindrical reactor can be calculated as follows:

$$V = V_a = V_v = (\pi r_a^2 l_a) - \frac{4}{3} \pi r_b^3 n \quad (3.10)$$

$$S = S_a = S_v = 4\pi r_b^2 n \quad (3.11)$$

$$r_v = \frac{2V}{S} \quad (3.12)$$

$$l_v = \frac{V}{\pi r_v^2} \quad (3.13)$$

where

- $V$  : Volume of the space that the OH freely moves,
- $V_a$  : Volume of the actual reactor,
- $V_v$  : Volume of the VCR,
- $S$  : Surface area that the material is coated on,
- $S_a$  : Surface area of the actual reactor,
- $S_v$  : Surface area of the VCR,
- $r_v$  : Radius of the VCR,
- $l_v$  : Length of the VCR,
- $r_a$  : Radius of the actual tube,
- $l_a$  : Length of the actual tube,
- $r_b$  : Radius of the bead,
- $n$  : Number of beads packed.

Figure 3.7 illustrates the transfer from a flow tube packed with beads to a virtual cylindrical reactor. Therefore, the residence time ( $t$ ) inside a virtual cylindrical flow tube can be determined as follows:

$$t = \frac{l_v}{v_v} = \frac{l_v \cdot \pi r_v^2}{W} = \frac{V}{W} \quad (3.14)$$

where  $v_v$  is the gas convective velocity of the virtual flow with a total flow,  $W$ . The calculated Reynolds number of 1300 suggests that a virtual flow is laminar while it does not really imply the same for an actual flow.

There is an alternate approach to compute the mass transfer rate in a packed-bead reactor, described in the chemical engineering literature [e.g. Fogler, 1999]; it involves the Sherwood (Sh), Schmidt (Sc), and Reynold (Re) numbers, and the Colburn

J factor. In a future study, this approach will be compared to the VCR approximation.

**Figure 3.7.** The schematic of conversion to a virtual reactor. The virtual reactor is typical cylindrical tube, while the actual reactor is filled with sixty beads, having the same volume and coated surface area as the actual reactor.

### 3.3.3.1. The Validity of the VCR Approximation

The validity of the VCR approximation was tested as follows. Paraffin wax was selected because of its well known reaction probability of OH [Bertram *et al.*, 2001]. In addition, its melting point is close to that of halocarbon wax ( $\sim 58^\circ\text{C}$ ) so that two waxes mix together homogeneously when solidified, enabling to control the reactivity of the mixture properly. Since the average molecular weights of paraffin wax and halocarbon wax (600 series) used in this work are close to 600 g/mole, the ratio of number of reactive sites is considered to be equal to the weight ratio under the assumption that each wax molecule provides one reactive site. Therefore, the reaction probability of the mixture,  $\gamma^{\text{mix}}$ , is determined by the following equation:

$$\gamma_{OH}^{\text{mix}} = \sum_j \beta_j \gamma_{OH}^j \quad (3.15)$$

where  $\gamma_j$  is the reaction probability of compound  $j$  in the mixture, and  $\beta_j$  is the fraction of compound  $j$ , which meets the condition of  $\sum_j \beta_j = 1$  and  $\beta_j = \frac{n_j}{\sum n_j}$ , where  $n_i$  is the number of active sites of compound  $j$ .

We prepared four different mixtures of paraffin wax and halocarbon wax, which were 1/130, 1/43, 1/20, and pure paraffin wax corresponding to 0.0012, 0.0037, 0.008, and 0.16 of reaction probabilities, respectively. The relative intensities of OH from these mixtures obtained from the experiment (■) are in agreement with the results of the virtual reactor approximation (solid line) as shown in Figure 3.8.

**Figure 3.8.** The estimated relative intensity of OH in a beads-packed reactor (solid line) and the experimental relative intensities of various mixtures of paraffin wax and halocarbon wax (■). The reaction probabilities of the mixtures are 0.16 (pure paraffin wax), 0.008 (1/20 paraffin wax), 0.0037 (1/43), and 0.0012 (1/130). The estimated relative intensity of OH in a conventional cylindrical tube (dashed line) was included for a comparison with a beads-packed system.

### 3.3.3.2. Beads-Packing Technique (Revisited)

The estimated relative OH intensity in a cylindrical tube without beads-packing (dashed line) is included in Figure 3.8 to confirm the necessity of beads-packing technique in this work (Section 2.4). Note that coating with a material of interest only on the wall of a flow tube resulted in a small probability for OH to collide with the walls at high pressure. The change in the relative intensity of OH in the beads-packing system was doubled when compared to that in a flow tube within the same change in  $\gamma_{OH}$ . This illustrates how the beads-packing technique enhances the sensitivity of  $R_{surface}$  by increasing the surface area.

### 3.3.3.3. Technique of Dilution for Better Sensitivity

For the highly reactive surface to OH resulting high value of  $k_{kin}$ , the additivity of kinetic resistances (Equation 3.3) expects that  $k_{obs}$  is mainly determined by the relatively low value of  $k_{dif}$ . In other words, the OH heterogeneous reactions on the highly reactive surface are screened by the diffusion of the radical to the wall even in our beads-packed system. As seen in Figure 3.8, the estimated relative intensity ( $R_{est}$ ) converges fast as  $\gamma_{OH}$  increases, especially from 0.01. For example,  $R_{est}$  changes only 0.016 in the range between  $\gamma_{OH} = 0.02$  and 0.03, while 0.1 in the range between  $\gamma_{OH} = 0.002$  and 0.003. Taking our systematic error in  $R_{surface}$  ( $\sim \pm 5\%$ ) into account, any changes in the reactions of high uptakes, even if any, are totally screened by diffusion. Therefore, we are not expected to observe any water effects on the OH heterogeneous reactions on the highly reactive materials due to the diffusion limitation.

Diluting materials with halocarbon wax (in the case of organic materials) or partial coating (in the case of inorganic materials in powder) enabled to escape from the

diffusion limitation. It was already shown above (Figure 3.8) that dilution of the material of interest effectively reduces the uptake of OH on the surface. This decrease in the uptake does not indicate a change in the chemistry, but rather a decrease in the extent of heterogeneous loss of OH on the surface. In other words, heterogeneous reactions of OH on the surface in the influence of RH take place for a reduced amount so that the chemistry is out of the diffusion limitation while the original values of  $\gamma_{\text{OH}}$  for the pure surface are still able to recover by considering the degree of dilution and/or surface coverage.

By this approach, the reaction probabilities of highly reactive materials were controlled to comparable values with diffusion, or approximately  $\gamma_{\text{OH}} = 0.001 \sim 0.002$ , corresponding to  $R_{\text{surface}} = 0.6 \sim 0.8$ . The specific example of the technique of dilution for better sensitivity is shown in Section 3.3.5.2.

#### 3.3.3.4. Determination of $\gamma_{\text{OH}}$ from $R_{\text{surface}}$

As discussed above, the reaction probability of OH,  $\gamma_{\text{OH}}$ , may be determined from the  $R_{\text{surface}}$  obtained using the  $r_v$  and  $t$  obtained from the VCR approximation, even though the experimental reaction time is fixed. An example for the determination of  $\gamma_{\text{OH}}$  from  $R_{\text{surface}}$  is shown in Appendix 3-III. In addition, the errors arising in the calculations propagated from the errors of measurements are shown in Appendix 3-IV.

### 3. 3. 4. OH-H<sub>2</sub>O Complexes

Due to its ability to form hydrogen bonds, water vapor clusters readily with various gaseous species in the atmosphere [Aloisio *et al.*, 2000; Hansen *et al.*, 2002; Sennikov *et al.*, 2005]. For example, much attention, both experimental and

theoretical, has been paid to the water dimer [Dyke *et al.*, 1977; Newton *et al.*, 1983; Feyereisen *et al.*, 1996]. On the other hand, the complex between OH and water molecule has been rarely studied. Experimental evidence for the existence of such complex has been rarely reported, while theoretical studies have only succeeded in estimating the structure and energy of the complex [Kim *et al.*, 1991; Dubey *et al.*, 1997; Wang *et al.*, 1999; Aloisio *et al.*, 2002; Karakus *et al.*, 2005; Sennikov *et al.*, 2005]. Although our study is focused on heterogeneous processes, it is worth considering OH-H<sub>2</sub>O complex formation through a gas-phase reaction since the two species were abundant in the gas phase, and therefore, the water complexes can affect our experimental observations [Hansen *et al.*, 2002].

In fact, the OH-H<sub>2</sub>O complex is an intermediate in the proton transfer reaction between OH and H<sub>2</sub>O [Dubey *et al.*, 1997]:

where the double dagger stands for the transition state. The theoretically calculated rate constant for the proton exchange reactions (3.16 ~ 3.17) is reported at  $2.94 \times 10^{-17} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 300 K [Uchimaru *et al.*, 2003]:

Additional complexes with additional water molecules, OH-(H<sub>2</sub>O)<sub>n</sub>, can be formed under conditions when OH-H<sub>2</sub>O collides with another water molecule before its self-dissociation or isomerization:

**Figure 3.9.** The structures of OH-H<sub>2</sub>O (a), OH-(H<sub>2</sub>O)<sub>2</sub> (b), and OH-(H<sub>2</sub>O)<sub>3</sub> (c) optimized with the B3LYP method and 6-31G(d,p) basis set. The structures of (a) and (b) belong to the C<sub>s</sub> point group.

*Ab initio* calculations for the three complexes between OH and water molecules, OH-H<sub>2</sub>O, OH-(H<sub>2</sub>O)<sub>2</sub>, and OH-(H<sub>2</sub>O)<sub>3</sub>, were performed in the present work to obtain their geometries and energy states. Geometries of the water complexes optimized at the global minima are shown in Figure 3.9. OH-H<sub>2</sub>O and OH-(H<sub>2</sub>O)<sub>3</sub> belong to the C<sub>s</sub> point group while OH-(H<sub>2</sub>O)<sub>2</sub> has no symmetry. The structure of OH-H<sub>2</sub>O is consistent with results of the previous works [Kim *et al.*, 1991; Xie *et al.*, 1993; Dubey *et al.*, 1997; Wang *et al.*, 1999; Aloisio *et al.*, 2002; Karakus *et al.*, 2005; Sennikov *et al.*, 2005]. The hydrogen bond is formed between the hydrogen atom of OH and the oxygen atom of H<sub>2</sub>O because OH accepts readily the electronic density. In OH-(H<sub>2</sub>O)<sub>3</sub>,

two additional water molecules form efficiently hydrogen bonds with OH-(H<sub>2</sub>O) from out of plane directions with approximately 2.5Å distance to the C<sub>s</sub> plane. OH-(H<sub>2</sub>O)<sub>2</sub> consists of a six-membered ring formed by the OH radical and two OH groups from the water molecules through hydrogen bonding.

### 3.3.4.1. Energy States of Water Complexes

The total energies and the Gibbs free energies of the reactants and the complexes at global minima are listed in Table 3.1. The binding energy of OH-H<sub>2</sub>O complex (-6 kcal/mol) is consistent with the results of previous works [Nanayakkara *et al.*, 1992; Xie *et al.*, 1993]. Further hydration with hydrogen bonding is expected to stabilize the complex with negative enthalpy changes ( $\Delta H_{n-1 \rightarrow n} < 0$ ) apart from how fast they proceed before a OH-H<sub>2</sub>O complex is dissociated.

**Table 3.1.** Summary of the energies of the various species (in Hartree)

Species	Total Energy <sup>a</sup>	Gibbs Free Energy	$\Delta H_{n-1 \rightarrow n}$ <sup>b</sup> (kcal/mol)
OH	-75.720061	-75.736997	
H <sub>2</sub> O	-76.398364	-76.416020	
OH-H <sub>2</sub> O	-152.127950	-152.153581	-6.0 (-5.7) <sup>c</sup>
OH-(H <sub>2</sub> O) <sub>2</sub>	-228.546261	-228.575091	-12.5
OH-(H <sub>2</sub> O) <sub>3</sub>	-304.956232	-304.989515	-7.3
OH...H <sub>2</sub> O <sup>d</sup>	-152.118299 <sup>e</sup>	-152.146902 <sup>e</sup>	

<sup>a</sup> Corrected by zero-point energy

<sup>b</sup> Enthalpy change for water hydration (OH-(H<sub>2</sub>O)<sub>n-1</sub> + H<sub>2</sub>O → OH-(H<sub>2</sub>O)<sub>n</sub>)

<sup>c</sup> Nanayakkara *et al.*, 1992; Xie *et al.*, 1993

<sup>d</sup> Loose complex for the substitution of a transition state. Details are described in Appendix 3-V.

<sup>e</sup> One imaginary frequency was ignored from the energy corrections.

### 3.3.4.2. Fraction of OH-H<sub>2</sub>O in the System

The information about the rates for the forward ( $k_{3.16}$ ) and the backward ( $k_{3.16}^{-1}$ ) reactions is necessary to determine the fraction of a OH-H<sub>2</sub>O complex gas phase; it can be estimated using the following equilibrium constant,  $K^{3.16}$ :

$$K_{3.16} = \frac{[OH \cdot H_2O]}{[OH][H_2O]} = \frac{k_{3.16}}{k_{3.16}^{-1}} \quad (3.21)$$

Since the rate constants for the reactions have not been determined, *ab initio* calculations were used to obtain the rate constants theoretically. At the level of B3LYP and MP2 theories, the transition state for Reaction 3.16 was not found, implying that an entrance barrier is extremely shallow or zero. Therefore, the reaction was assumed to proceed whenever the reactants collide together in a proper orientation. The rate constant of Reaction 3.16 ( $k_{3.16}$ ) within the reactive hard-sphere model was estimated to be  $1.1 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  at 298 K. Due to the low binding energy of the water complex and the shallow barrier, the lifetime of the water complex is extremely short ( $1.9 \times 10^{-10} \text{ s}$ ) with  $k_{3.16}^{-1} = 5.3 \times 10^9 \text{ s}^{-1}$  at 298 K.

Since the equilibrium constant ( $K_{3.16}$ ) was determined as  $2.1 \times 10^{-26} \text{ cm}^3 \text{ molecule}^{-1}$  using  $k_{3.16}$  and  $k_{3.16}^{-1}$ , the concentration of OH-H<sub>2</sub>O complex was estimated to be  $5.3 \times 10^2 \text{ molecule cm}^{-3}$  corresponding  $6.6 \times 10^{-10}$  as the fraction of the water complex in the gas-phase. The possibility of the existence for a OH-(H<sub>2</sub>O)<sub>n</sub> complex in the gas phase was excluded due to its negligible fraction and the extremely short life time of the complex. The details about the determination of the rate constants are described in Appendix 3-V.

In fact, OH-(H<sub>2</sub>O)<sub>n</sub> complexes was observed as RH increased as mentioned in Section 2.1.7. Although a possible origin of the water clusters can have two reasons, the first one (Reactions 3.16 and 3.22) should be excluded for the reason stated above.

or,

The equilibrium in the Reaction 3.24 is believed to shift to the left because of thermodynamically deep wells of the complexes (-36.5 kcal/mol). The results of the *ab initio* calculations for the energy of the  $\text{OH}^-(\text{H}_2\text{O})_n$  complexes are listed in Table 3.2.

**Table 3.2.** The summary of the energies of the species (in Hartree) (B3LYP)

Species	Total Energy <sup>a</sup>	$\Delta H_{n-1 \rightarrow n}$ <sup>b</sup> (kcal/mol)
$\text{OH}^-$	-75.718319	-
$\text{H}_2\text{O}$	-76.398364	-

<sup>b</sup> Enthalpy change for water hydration  $\text{OH}^-(\text{H}_2\text{O})_{n-1} + \text{H}_2\text{O} \rightarrow \text{OH}^-(\text{H}_2\text{O})_n$

### 3. 3. 5. Organic Surfaces

#### 3.3.5.1. Determination of $\gamma_{\text{OH}}$ under Dry Conditions

We first determined the OH reaction probabilities for pure organic surfaces, such as paraffin wax, pyrene, glutaric acid, and methane-soot, under dry conditions for verification of the suggested VCR method. First, the relative intensity of OH,  $R_{\text{OH}}$ , for the pure organic surfaces was experimentally measured followed by determining  $\gamma_{\text{OH}}$  as

described in Section 3.3.3.4. Results of the uptake measurements are shown in Table 3.3; for comparison, literature values for the same organic surfaces are shown as well. As seen from the table, the experimental results obtained based on the VCR approximation reproduce reasonably well the literature values, although the range of the measured reaction probability values is wider due to the worse sensitivity of the VCR method to high uptake values, as discussed above.

**Table 3.3.** The OH reaction probability for the organics under the dry condition.

surface	R	$\gamma_{OH}$	references
paraffin wax	$0.281 \pm 0.016$	0.03 - 1	present work
		0.16 - 1	[Bertram <i>et al.</i> , 2001]
pyrene	$0.270 \pm 0.008$	0.03 - 1	present work
		0.15 - 1	[Bertram <i>et al.</i> , 2001]

### 3.3.5.2. The Effect of Relative Humidity

The effect of water vapor on OH uptake by organic materials was studied for the pure and diluted surfaces. As most of the organics studied are highly reactive to OH, resulting in a high value for  $k_{kin}$  due to the diffusion limitation, a water effect on OH uptake was not expected. For this reason, the organic surfaces were diluted with halocarbon wax to give a net  $\gamma_{OH}$ -value in the region of  $(1-2) \times 10^{-3}$  that corresponds to  $R_{surface} = 0.6 - 0.8$  where the sensitivity of the VCR method is the best (See Section 3.3.3.3).

**Figure 3.10.** The relative intensities of OH ( $R_{OH}$ ) for pure (■) and diluted (○) surfaces of pyrene (a), and glutaric acid (b) under various relative humidity conditions. There are no changes in  $R_{OH}$  on both pure organic surfaces, whereas only the diluted surface of glutaric acid changed.

Figure 3.10 illustrates how the surface dilution technique works. No changes in  $R_{OH}$  under wet conditions were observed for pure surfaces of pyrene (a) and glutaric acid (b). However, it appears ambiguous that no change on highly reactive surface implies no water effect since the diffusion of OH limits our observation as described above. The observation becomes much clearer for the diluted surfaces. We observed a decrease in  $R_{OH}$  on the diluted surface of glutaric acid, whereas still no change on that of pyrene. (Controlling the net OH reaction probability by dilution was applied not only to highly reactive organic materials, but also to most materials studied, except  $\text{CaCl}_2$ ,  $\text{MgCl}_2$ , and sea salt, used in this work to increase sensitivity.)

The effect of relative humidity on  $R_{OH}$  for the diluted paraffin wax and methane soot surfaces of known composition was also studied. Subsequently applied Equation 3.9 and 3.15, we were able to retrieve the OH reaction probability values for the pure organic and methane soot surfaces. The details about the determination of  $\gamma_{OH}$  for the pure organic surfaces based on measurements of  $R_{OH}$  for diluted surfaces are described in Appendix 3-VI.

The results of these experiments are shown in Figure 3.11 and Table 3.4. Only an initially hydrophilic organic surface, such as glutaric acid, shows the enhancement in its reactivity towards OH, whereas for paraffin wax and pyrene surfaces no noticeable changes in  $\gamma_{OH}$  within experimental error were observed under wet conditions. More attention is required for methane soot since only small decrease in  $\gamma_{OH}^{soot}$  was observed at low RH. Focused on the region of small RH change ( $\text{RH} < 9\%$ ),  $\gamma_{OH}$  on the methane soot surface ( $\gamma_{OH}^{soot}$ ) dropped by approximately 40%. In contrast, further increase in RH was relatively insensitive for change in OH uptake.

**Figure 3.11.** The dependences of  $\gamma_{OH}$  for paraffin wax (a), pyrene (b), glutaric acid (c), and methane soot (d) on RH.

<sup>a</sup>  $\gamma_{OH}$  were not measured at these RH conditions.

Whereas fresh soot is extremely hydrophobic and repels water, soot becomes hydrophilic due to the formation of oxygen-containing groups on the surface upon OH exposure [Molina *et al.*, 2004; Zuberi *et al.*, 2005]. Since the freshly prepared soot surface was pre-treated by OH for an hour before our measurements, the aged soot surface was believed to allow for water adsorption on the surface. Therefore, there is the possibility that adsorbed water adlayer will cover surface active sites, resulting in their screening from OH, and lowering  $\gamma_{OH}^{soot}$  under wet conditions, which can be responsible for the decrease in  $\gamma_{OH}^{soot}$  at low RH. However, in fact, the extent of changes in the hydrophilicity of a soot surface upon OH exposure is small [Zuberi *et al.*, 2005], making this explanation less plausible. In the range of the RH (0 - 50%) in our

experiments, even aged soot takes up only a small amount of water [Zuberi *et al.*, 2005] which is not enough to screen surface site available for OH uptake.

Coming back to Figure 3.11 (d), the first change in  $\gamma_{OH}^{soot}$  was 40%. Considering that the possible uncertainty of  $\sim 25\%$  in  $\gamma_{OH}$  arising from error propagation is approximately 25% (Appendix 3-IV), a 40% change is not sufficient to determine the water effect on  $\gamma_{OH}^{soot}$ . Moreover, the uncertainty in the  $\gamma_{OH}^{soot}$  value obtained at 48% RH overlaps with the whole range of the change in  $\gamma_{OH}^{soot}$ . Therefore, additional study on this issue with enhanced sensitivity and accuracy is required to determine the water effect on  $\gamma_{OH}^{soot}$ .

The obtained results on the change in  $\gamma_{OH}$  on paraffin wax, pyrene, and methane soot (Figure 3.11 (a), (b), and (d)) suggest that OH exposure does not alter the hydrophilicity of organic and soot surfaces to such extent to influence OH uptake. Therefore, water molecules in a humid environment are not adsorbed efficiently on the carbonaceous surfaces in order to noticeably affect OH uptake. This conclusion is in agreement with results previous results from our laboratory on the OH-initiated oxidation of organic and soot surfaces [Molina *et al.*, 2004].

On the other hand, a hydrophilic organic surface with a relatively higher water adsorption capacity may exhibit a change in OH reactivity in a different (liquid) environment. Glutaric acid, a dicarboxylic acid, can be an example of such initially hydrophilic organic surface (Figure 3.11 (c)). The first step of the OH heterogeneous interaction with organic materials is the H-abstraction reaction [Bertram *et al.*, 2001].

where R-H is a alkane and R $\cdot$  is a alkyl group. As the C—H bond in alkane becomes

less strong, a lower activation energy for hydrogen abstraction could be caused for a faster reaction rate. Although the rest of the C—H bonds in glutaric acid are not expected to be influenced by water adsorption, O—H bonds in carboxylic functional groups may weaken through electron density stabilization by surrounding water [Reichardt, 1994; Woods III *et al.*, 2005]. As a result, the carboxylic H may be more easily abstracted, leading to higher OH uptake.

The reaction mechanism for OH uptake at higher RH conditions may change from radical to ionic. For example, assuming that water molecules are preferentially adsorbed on carboxylic functional groups, as more water is taken up by a surface, a higher degree of dissociation of glutaric acid can occur. OH may react more efficiently with dissolved ions: for example, OH uptake was enhanced by a factor of 25 on sulfuric acid as compared to that on pure water [Hanson *et al.*, 1992]. Therefore, weakening an O—H bond in carboxylic groups and the acidic dissociation can be responsible for the observed enhancement by a factor of 4 in the OH reaction probability at 48% of RH (Figure 3.11 (c)).

### 3.3.6. Inorganic Surfaces

We have also measured the relative OH intensity ( $R_{OH}$ ) for inorganic materials of tropospheric importance followed by determining the reaction probabilities of OH under dry conditions as shown in Table 3.5. For direct measurements, the pure surface material was used (no dilution). Few studies have been carried out on the heterogeneous reactions of OH with inorganic salts up to date; to our knowledge, our study presents the first reported OH reaction probabilities on  $MgCl_2$ ,  $Na_2SO_4$ ,  $CaCl_2$ , and KCl. Consistency of  $\gamma_{OH}$  for NaCl, sea salt and  $Al_2O_3$  with the literature values

provides support for our experimental approach [Ivanov *et al.*, 1996; Gratpanche *et al.*, 1996; Bertram *et al.*, 2001].

**Table 3.5.** The OH reaction probability for inorganic materials under dry conditions.

Surface	R	$\gamma_{\text{OH}} (\times 10^{-3})$
NaCl	$0.469 \pm 0.012$	$4.6 [\pm 0.7]$ 4 <sup>a</sup>
MgCl <sub>2</sub>	$0.428 \pm 0.008$	$6.1 [\pm 1.2]$

<sup>a</sup> Ivanov *et al.*, 1996

<sup>b</sup> Gratpanche *et al.*, 1996

<sup>c</sup> Suh *et al.*, 2000

<sup>d</sup> Bertram *et al.*, 2001

Approximately one order of magnitude difference in  $\gamma_{\text{OH}}$  on SiO<sub>2</sub> from the reported value obtained on fused quartz [Suh *et al.*, 2000] was observed. The variation possibly arised from the origin of SiO<sub>2</sub> as Suh and the coworkers explained for their unexpected small value.

### 3.3.6.1. Sea Salt and its Components

The VCR method together with a surface dilution technique was successfully applied in the present uptake experiments for sea salt and its five major components, NaCl (68%), MgCl<sub>2</sub> (14%), Na<sub>2</sub>SO<sub>4</sub> (11%), CaCl<sub>2</sub> (4%), and KCl (2%), to investigate the effect of relative humidity on the heterogeneous reaction of OH. The OH reaction probabilities for the salts measured under dry and wet conditions (0 to 48% of RH) are shown in Figure 3.12 and also listed in Table 3.6.

The reaction probability values for the hygroscopic salts (MgCl<sub>2</sub>, CaCl<sub>2</sub>, and sea salt) are not available at high RH conditions because the salts were deliquesced before reaching those RH. Deliquescence is a phase transformation whereby a solid absorbs water vapor from the atmosphere, leading to the dissolution of the solid. It occurs at deliquescence relative humidity point (DRH), when the RH is equal to the vapor pressure of the corresponding solution. The DRH's of CaCl<sub>2</sub> (hexahydrate, CaCl<sub>2</sub>·6H<sub>2</sub>O) and MgCl<sub>2</sub> (hexahydrate, MgCl<sub>2</sub>·6H<sub>2</sub>O) are 29% RH and 33% RH, respectively [Linke, 1965; Wagman *et al.*, 1982; Lide, 2007]. However, the observed DRH of CaCl<sub>2</sub> and MgCl<sub>2</sub> were found to be 24% RH and 35% RH, respectively, explained by the fact that the hydration was incomplete in short time frames resulting in mixtures of tetra- and hexa-hydrates. The DRH of sea salt was observed at ~40%, which is consistent with the recent report for the deliquescence in binary mixtures [Salameh *et al.*, 2005]. Since the deliquesced solution could not stay on a bead surface under a fast flow environment, the salt was washed out from the beads causing irreversible changes in salt-coating morphology.

**Figure 3.12.** The dependences of  $\gamma_{OH}$  for NaCl (a),  $MgCl_2$  (b),  $Na_2SO_4$  (c),  $CaCl_2$  (d), KCl (e), and sea salt (f) on RH.

48	- <sup>a</sup>	- <sup>b</sup>	2.5 ± 0.3	- <sup>b</sup>	3.1 ± 0.3	- <sup>b</sup>

<sup>a</sup>  $\gamma_{\text{OH}}$  were not measured at these RH conditions.

<sup>b</sup> The salts were deliquesced.

Noticeable changes in the OH reaction probability were observed at 0 - 48% of RH for the highly hygroscopic salts ( $\text{MgCl}_2$ ,  $\text{CaCl}_2$ , and sea salt), but not for less hygroscopic salts ( $\text{NaCl}$ ,  $\text{Na}_2\text{SO}_4$ , and  $\text{KCl}$ ). We observed that as RH increases,  $\gamma_{\text{OH}}$  on  $\text{MgCl}_2$  increased by factor of 1.7 at 20% of RH as compared to the dry condition value. However,  $\text{CaCl}_2$  showed opposite changes in  $\gamma_{\text{OH}}$ . The  $\gamma_{\text{OH}}$  value for  $\text{CaCl}_2$  decreased by factor of 3.2 at 20% RH as compared to dry conditions. Although a small decrease in  $\gamma_{\text{OH}}$  was observed for  $\text{KCl}$  as well, the water effect is uncertain due to the same reason as the case of methane soot (Section 3.3.5.2). Interestingly, sea salt showed a positive effect of water on  $\gamma_{\text{OH}}$  following  $\text{MgCl}_2$ , rather than  $\text{NaCl}$ , its major component.

#### **3.3.6.1.1. Redistribution of ions at the surface**

Absorbed water can influence OH uptake by salt materials due to a surface redistribution effect of salt ions. It has been reported that large polarizable anions are more readily available at a surface than relatively small and less polarizable cations [Jarvis *et al.*, 1968; Petersen *et al.*, 1999; Knipping *et al.*, 2000; Ghosal *et al.*, 2005]. Cations are thought to fit more easily into the hydrogen-bonded water structure upon solvation, whereas anions are too large [Knipping *et al.*, 2000]. Therefore, water extracts the small nonpolarizable cations to the bulk from the interface (surface). As a result, ions are redistributed near the surface according to their size and polarizability.

At this point, attention needs to be paid to define the surface and the bulk since it determines the way of the redistribution of the surface ions. In a solution, the bulk is the side that is abundant in water, while the surface is the other side exposed to the gas-phase. Therefore, due to its larger size and higher polarizability, anions are pushed out from the bulk to the surface interface while cations stay in the bulk [Jarvis *et al.*, 1968].

In our system of present work, however, the bulk is defined as inside of the salt solid, which is dry, whereas the surface is relatively abundant in water. As a consequence, water in the surface extracts cations from the bulk making them abundant on the surface interface under wet conditions.

The redistribution of surface ions is not limited to the fully wetted conditions at RH higher than their deliquescence. Even at low RH ( $\sim 2\%$ ), ionic mobility is found to be enhanced, leading to the efficient redistribution of the surface ions [Hemminger, 1999] even though the extent of ion redistribution is a strong function of RH. It was found that the following factors are important in characterization of the surface ion redistribution:

- (1) *The size of ion*
- (2) *The polarizability of ion*
- (3) *Relative humidity*

The radii and polarizabilities of ions in NaCl, MgCl<sub>2</sub>, KCl, and CaCl<sub>2</sub> are summarized in Table 3.6. Since MgCl<sub>2</sub> and CaCl<sub>2</sub> exist as hydrated complexes under wet conditions, ionic radii for the higher coordination number (CN) are also listed. The order of ionic radii for ions with CN = 6 is  $\text{Mg}^{2+} < \text{Na}^+ \sim \text{Ca}^{2+} < \text{K}^+ < \text{Cl}^-$ . As can be seen from the ionic radius order,  $\text{Mg}^{2+}$  is expected to be the most active in the surface ion redistribution. Although  $\text{K}^+$  is the least favorable ion due to its large ionic size, it is still more abundant on a wet surface as compared to even larger anions, such as  $\text{Cl}^-$ .

The ion radii of  $\text{Na}^+$  and  $\text{Ca}^{2+}$  with CN = 6 are very close to each other. However, accounting for its higher coordination number and higher polarizability,  $\text{Ca}^{2+}$  is less favorable to be extracted by water from the bulk to the surface as compared to

$Mg^{2+}$  or  $Na^+$ . Therefore, the efficiency of the surface ion redistribution at given RH is thought to follow the following order:

$$Surface \leftarrow Mg^{2+} < Na^+ < Ca^{2+} < K^+ < Cl^- \rightarrow Solid Bulk$$

This order can be applied not only to an individual salt, but also to a salt mixture, such as sea salt, leading to segregation effect as discussed in Section 3.3.6.1.3.

### 3.3.6.1.2. The effect of the surface ion redistribution on OH uptake

The change in a cation surface concentration can influence OH uptake due to the following surface effects:

(1) *Screening the available site for OH uptake (F1)*

(2) *Acidification of the surface (F2)*

The first effect (F1) reduces  $\gamma_{OH}$ , while the second effect (F2) increases  $\gamma_{OH}$  as RH increases. These two opposite factors compete with each other, and therefore, the net effect is determined by the type of ions in the salt molecule, and by the RH condition.

The OH radical is an electron acceptor for which it is favorable to fill its  $\pi$

orbital. The OH electron affinity is 1.828 eV [Goldfarb *et al.*, 2005], which is greater than that of O (1.461 eV [Neumark *et al.*, 1982]) and a half of that of Cl (3.613 eV) [Berzinsh *et al.*, 1995]. This implies that OH prefers an anion to an electron-deficient cation as an uptake site. Therefore, as anions are deficient in the surface, less OH uptake occurs on those sites.

The redistribution of ions results in an anion deficiency near the surface. The molecular dynamics simulations for a model salt surface (NaCl)<sub>96</sub>(H<sub>2</sub>O)<sub>864</sub> by Knipping *et al.* [2000] showed the significant separation of the anion and the cation on the gas-wet solid interface, indicating that the surface cation concentration prevails over of the surface anion concentration depending on the degree of redistribution of the surface ions. As a consequence, the active sites available for OH uptake, ie, Cl<sup>-</sup>, are screened by abundant cations and/or adsorbed water molecules decreasing  $\gamma_{OH}$ .

A similar effect was observed by Remorov *et al.* (2002) in a study of HO<sub>2</sub> uptake on NaCl. They reported a decrease in the HO<sub>2</sub> uptake on NaCl at a pressure of 0.1 Torr. Although the redistribution of ions was not taken into account, they successfully explained that the phenomenon by inhibition of water vapor reducing the number of the free sites available for adsorption of HO<sub>2</sub>.

According to the reaction mechanism proposed early [Oum *et al.*, 1998; Finlayson-Pitts *et al.*, 2000], OH uptake on NaCl is extremely sensitive to surface pH since the reaction with H<sup>+</sup> (Reaction 3.28) is involved, which is considered to be the rate determining step:

The detailed reaction mechanism is described in Appedix 3-VII.

The ion redistribution changes the surface pH with the efficiency dependant on the cation. To explain this dependence, other related facts must be taken into consideration. It has been reported that a water molecule can efficiently dissociate upon its adsorption on a surface with defects to form surface OH<sup>-</sup> [Fölsch *et al.*, 1991; Dai *et al.*, 1995; Hemminger, 1999; Ghosal *et al.*, 2004] although the mechanism is still unknown. The surface remains neutral as H<sup>+</sup> and OH<sup>-</sup> are produced together.

Also, it should be mentioned that water dissociates in the liquid bulk to produce the same products with  $K_w = 1.0 \times 10^{-14}$ , where  $K_w$  is the dissociation constant.

Magnesium hydroxide (Mg(OH)<sub>2</sub>) and calcium hydroxide (Ca(OH)<sub>2</sub>) are insoluble in water with the solubility product constants ( $K_{sp}$ ) of  $5.61 \times 10^{-12} \text{ mole}^3 \text{ L}^{-3}$  and  $5.02 \times 10^{-6} \text{ mole}^3 \text{ L}^{-3}$ , respectively [Wagman *et al.*, 1982; Lide, 2007].

$$K_{sp}(\text{Mg(OH)}_2) = [\text{Mg}^{2+}] \cdot [\text{OH}^-]^2 = 5.61 \times 10^{-12} \quad (3.31)$$

$$K_{sp}(\text{Ca(OH)}_2) = [\text{Ca}^{2+}] \cdot [\text{OH}^-]^2 = 5.02 \times 10^{-6} \quad (3.32)$$

Therefore, cations at high concentrations precipitate due to their reaction with OH<sup>-</sup> produced from Reactions 3.29 and 3.30. As OH<sup>-</sup> is removed from the surface interface according to Le Châtelier's Principle, surface pH decreases.

Although it is assumed that  $K_w = 1.0 \times 10^{-14}$  is valid for Reaction 3.30 at the macroscopic scale (several water monolayers), the surface concentration of OH<sup>-</sup> produced on surface defects (Reaction 3.29) is not known. Assuming that the two reactions are comparable, [OH<sup>-</sup>] can be estimated at  $2 \times 10^{-7} \text{ mole L}^{-1}$ , and using this value in Reactions 3.31 and 3.32, the surface Mg<sup>2+</sup> and Ca<sup>2+</sup> concentrations to be precipitated can be estimated at  $140 \text{ mole L}^{-1}$  and  $1.26 \times 10^8 \text{ mole L}^{-1}$ , respectively.

Since the latter is highly unlikely, it may be concluded that  $\text{Ca}^{2+}$  does not noticeably change the surface pH. Moreover, the degree of surface  $\text{Ca}^{2+}$  and  $\text{Cl}^-$  redistribution is much less than that for  $\text{Mg}^{2+}$  and  $\text{Cl}^-$  ions due to the larger size of  $\text{Ca}^{2+}$  (Section 3.3.6.1.1), implying  $[\text{Ca}^{2+}] < [\text{Mg}^{2+}]$ .

Due to the uncertainties in  $[\text{OH}^-]$  and  $[\text{Mg}^{2+}]$ , it is difficult to determine if  $\text{Mg}^{2+}$  precipitates efficiently with  $\text{OH}^-$  ions. A concentration of  $[\text{Mg}^{2+}] = 140 \text{ mole L}^{-1}$  is unlikely because the  $\text{MgCl}_2$  solubility is  $5.9 \text{ mole L}^{-1}$  [Lide, 2007; Phase diagrams for ceramists, Volumes 1-8; ACerS-NIST Phase equilibrium diagrams, 1964-2001]. If significant relocation of  $\text{Mg}^{2+}$  into the surface by the redistribution of the surface ions is taken into account, however, an order of magnitude increase in its concentration may be possible.

Although precipitation does not occur,  $\text{OH}^-$  may still be removed via the following extremely favorable reaction ( $K_{3.33} = 380$ ) [Stock *et al.*, 1948; Harris, 1991]:

As a result, the surface pH is lowered, favored by Reaction 3.28, causing an enhancement of OH uptake. In addition, this effect becomes greater at higher RH since the degree of the redistribution of the surface ions depends on RH.

Unfortunately, quantification of  $[\text{H}^+]$  and the resulting change in  $\gamma_{\text{OH}}$  cannot be done accurately since the production rate in Reaction 3.29 is unknown. Additionally, the mechanism of OH uptake on a salt surface (Appendix 3-VII) is not yet well understood, although the qualitative estimation for change in  $\gamma_{\text{OH}}$  under wet conditions depending on salt is enabled as described above.

Recalling the beginning of this section, the overall relative humidity effect on OH uptake is determined by two competing factors ( $F1$  and  $F2$ ), and depends on nature

of a salt surface. For  $\text{MgCl}_2$ , the surface acidification (*F2*) prevails over the screening by water adsorption the surface sites available for OH uptake (*F1*). As a result,  $\gamma_{\text{OH}}$  on  $\text{MgCl}_2$  was enhanced as RH increased (Figure 3.12 (b)). In contrast, *F2* does not work for  $\text{CaCl}_2$ , while *F1* does, and therefore, OH uptake on  $\text{CaCl}_2$  is decreased under wet conditions (Figure 3.12 (d)).

The same consideration can be applied to NaCl and KCl. As NaOH and KOH are extremely soluble, precipitation is not expected. However, the amount of adsorbed water on NaCl and KCl available to screen the surface sites from OH uptake is less than that on  $\text{CaCl}_2$  at given RH due to the lower hydrophilicity of  $\text{CaCl}_2$ . Indeed, no noticeable change in  $\gamma_{\text{OH}}$  was observed (Figures 3.12 (a) and (e)). Assuming that the DRH is an appropriate measure of hydrophilicity, NaCl and KCl are less sensitive to change within a factor of 2.5 in RH than  $\text{CaCl}_2$  since the DRH values for NaCl, KCl and  $\text{CaCl}_2$  are 75%, 84% and 29%, respectively [Linke, 1965; Wagman *et al.*, 1982; Lide, 2007]. Although any noticeable change in  $\gamma_{\text{OH}}$  for NaCl and KCl were not observed in the range of 0 - 48% RH, lowering  $\gamma_{\text{OH}}$  is still anticipated in accordance with *F2* as RH approaches DRH.

The fact that a cation determines the water effect on OH uptake for its salt was confirmed by the observation for the two pairs of salts mixtures:  $\text{MgCl}_2$ - $\text{MgSO}_4$ , and NaCl- $\text{Na}_2\text{SO}_4$ . In addition to the five major components of sea salt, we performed additional uptake measurements for magnesium sulfate ( $\text{MgSO}_4$ ) to study the role of cations in the effect of RH on OH uptake. As seen in Figure 3.13,  $\gamma_{\text{OH}}$  on  $\text{MgSO}_4$  increased with RH, which is the similar effect as for  $\text{MgCl}_2$ . Recalling Figure 3.12 (a) and (c) for the other salt pair,  $\text{Na}_2\text{SO}_4$  showed no change as the same was observed for NaCl. Based on the results of these experiments, we conclude the following:

(1) *Cations are more important in determining the effect of relative humidity on OH uptake by a salt surface.*

(2) *Anions provide the reaction sites for OH uptake.*

**Figure 3.13.** The dependence of  $\gamma_{OH}$  for  $MgSO_4$  on RH. Note that the scale for the x axis ( $\gamma_{OH}$ ) is wider than those in Figure 3.12 to show the full range of change.

#### 3.3.6.1.3. Sea Salt

The most interesting observation was sea salt, a mixture of different salt components. As shown in Figure 3.12 (f), the water effect on OH uptake by sea salt followed patterns specific for  $MgCl_2$  rather than its major constituent,  $NaCl$ . The enhancement by a factor of 2.7 in  $\gamma_{OH}$  for sea salt was observed at 0-38% of RH.

To determine which component(s) drive this reactivity, we studied two different salt mixtures. One was, so called, 'synthetic sea salt' which consisted of the same components in the same ratio as the real sea salt. In the other mixture, so called,

‘synthetic sea salt without  $\text{MgCl}_2$ ’, only  $\text{MgCl}_2$  was removed from the synthetic sea salt. As shown in Figure 3.14, the synthetic sea salt reproduced the sea salt regarding water effect on OH uptake, while the other without  $\text{MgCl}_2$  followed NaCl reactivity with no changes observed. Therefore,  $\text{MgCl}_2$  is likely responsible for the observed effect of water vapor on  $\gamma_{\text{OH}}$  for sea salt.

**Figure 3.14.** The dependence of  $\gamma_{\text{OH}}$  for sea salt (■), synthetic sea salt (□), and synthetic sea salt without  $\text{MgCl}_2$  (△) on RH.

This may be explained by the segregation effect due to surface ion redistribution. In a multicomponent salt, such as sea salt, cations are redistributed by adsorbed water according to the order described in Section 3.3.6.1.1. For example, Dementiev *et al.* [2004] observed a similar segregation effect in a mixture of  $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$  and NaCl. After exposure to water vapor for 10-15 min, the

$[\text{Mg}^{2+}]/[\text{Na}^+]$  molar ratio on the surface was enhanced from 0.043 to 1.2, which is quite consistent with the concept of the ion redistribution described in Section 3.3.6.1.1. As a result,  $\text{Mg}^{2+}$  becomes the most abundant cation on the sea salt surface under wet conditions, regardless of the average fraction in the bulk determining the overall effect of water on OH uptake by sea salt.

### 3.3.6.2. Mineral Dust Particles

Figure 3.15 and Table 3.7 show the observed enhancement in  $\gamma_{\text{OH}}$  for  $\text{SiO}_2$  (silica) and  $\text{Al}_2\text{O}_3$  (alumina) with increasing RH. The observed enhancement for silica and alumina are factors of 3 and 2, respectively, at RH of up to 38%.

A reaction mechanism for OH uptake on silica and alumina has not been proposed yet. However, surface-catalyzed bimolecular reactions following the Langmuir-Hinshelwood (L-H) and Eley-Rideal (E-R) mechanisms [Steinfeld *et al.*, 1998] may be involved. The extremely strong covalent bonding network in silica and alumina do not allow any direct abstractions (as in the reactions of OH on organics) or substitutions through reaction steps (as in the reactions of OH on inorganic salts) by the OH radical. It should be noted that the melting points of silica and alumina are  $1722^\circ\text{C}$  (cristobalite) and  $2054^\circ\text{C}$  ( $\alpha$  type), respectively, whereas those of NaCl and  $\text{MgCl}_2$  are much lower at  $800^\circ\text{C}$  and  $822^\circ\text{C}$ , respectively

**Figure 3.15.** The dependence of  $\gamma_{OH}$  for  $SiO_2$  (a) and  $Al_2O_3$  (b) on RH

**Table 3.8.** The OH reaction probability for SiO<sub>2</sub> and Al<sub>2</sub>O<sub>3</sub> under various RH conditions

RH (%)	$\gamma_{\text{OH}} (\times 10^{-2})$	
	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>
0	3.2 ± 0.7	4.5 ± 0.5

38	<sup>a</sup>	8.4 ± 1.2

<sup>a</sup>  $\gamma_{\text{OH}}$  were not measured at these RH conditions.

(1) *Langmuir-Hinshelwood (L-H) Mechanism*

$$R_{L-H} = \frac{k_{3.35} K_{3.33} [\text{A}] K_{3.34} [\text{B}] S_0^2}{(1 + K_{3.33} [\text{A}] + K_{3.34} [\text{B}])^2} \quad (3.37)$$

(2) *Eley-Rideal (E-R) Mechanism*

$$R_{E-R} = \frac{k_{3.37} K_{3.33} [\text{A}] p_B S_0}{1 + K_{3.33} [\text{A}]} \quad (3.39)$$

where, A and B are the reactants (may be the same species), S is a site on the surface,  $R$  is the rate of product formation,  $k$  is the rate constant,  $K$  is the equilibrium constant for the adsorption process,  $S_0$  is the number of available binding sites, and  $p_B$  is the gas pressure of B [Steinfeld *et al.*, 1998].

It has been known that the surface of silica and alumina are hydroxylated upon the dissociation of the adsorbed water leading to formation of surface Si-OH and Al-OH [Schaefer *et al.*, 1984; Nishijima *et al.*, 1986; Chen *et al.*, 1986; Thiel *et al.*, 1987; Elam *et al.*, 1998; Fu *et al.*, 2006]. Si-H formation upon water dissociation was also observed [Schaefer *et al.*, 1984; Nishijima *et al.*, 1986] while no observation for Al-H was reported.

The formation of Si-OH and Al-OH (and Si-H in the case of silica) upon the dissociation of adsorbed water molecules provides a higher probability for reaction with OH via the L-H or E-R process. More specifically, formation of Si-OH and Al-OH increases the amount of A·S due to Reaction 3.34, leading to a higher value of  $K_{3.34}[A]$  in Equations 3.37 and 3.39. As a consequence, the product formation rate ( $R_{L-H}$  and  $R_{E-R}$ ) is enhanced although it still depends on the steps involving OH, such as Reactions 3.35, 3.36, and 3.38. Unfortunately, the estimation of the water effect on  $\gamma_{OH}$  for silica and alumina by quantification of the variables in the two catalytic mechanisms is not available. However qualitatively, it can be expected that the hydroxylation of silica and alumina by the adsorbed water causes increases in OH loss by its uptake on silica and alumina under wet conditions.

The products of the OH surface-catalyzed bimolecular reactions with the mineral dust surfaces likely include water and hydrogen peroxide ( $H_2O_2$ ). The  $H_2O_2$  released from the surface can further react with OH in the gas-phase:

with the rate constant  $k_{3.40} = 1.7 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Atkinson *et al.*, 2004]. While OH loss in Reaction 3.40 is negligible at  $[\text{OH}] = 8 \times 10^{-12} \text{ molecule cm}^{-3}$ ,  $\text{H}_2\text{O}_2$  was not detected in the gas phase likely because of the slow rate of electron transfer from  $\text{SF}_6^-$ . Therefore, switching the reagent ion to  $\text{O}_2^+$  for a higher CIMS sensitivity would increase the ability to detect  $\text{H}_2\text{O}_2$ .

with  $k_{3.41} = 1.5 \times 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Lindinger *et al.*, 1975]

We observed that  $\gamma_{\text{OH}}$  on alumina reached a maximum at approximately 14% RH as seen in Figure 3.15 (b). Coming back to the expression of the rate of product formation (Equations 3.37 and 3.39), the efficient hydroxylation of silica and alumina by water adsorption (corresponding A·S in Reaction 3.34),  $K_{3.34}[\text{A}] \gg 1$ , can lead to this saturation effect for since the adsorption of OH corresponding to Reactions 3.35, 3.36, and 3.38 is relatively slow. Therefore, it is suggested that the water adsorption on alumina is faster than that on silica, and hence becomes saturated at 14% RH.

### 3. 4. Atmospheric Implications

The results obtained show that the OH reaction probability is RH dependent for both initially hydrophilic organic surfaces and inorganic surfaces reaching higher values in comparison with those measured early under dry conditions. These high  $\gamma_{\text{OH}}$ -values become important for atmospheric modeling in which interactions with aerosol particles are included. A mechanism of such interactions and the RH effect can vary depending on the chemical composition and a mixed state of aerosol particles and a gas-phase environment but it is clear that it does not change a concentration level of OH in the

troposphere. Meanwhile, OH exposure can initiate and be ultimately responsible for chemical aging of atmospheric aerosol particles modifying their physical and chemical properties. It can lead to change in cloud condensation nuclei (CCN) ability of aerosols and their radiative forcing as well as to produce and release photochemically active gas-phase products.

The reactivity of sea salt under wet conditions was observed in the present study to be determined by its lower deliquesced component, namely  $\text{MgCl}_2$ . On the other hand, the efficiency of  $\text{Cl}_2$  production in the reaction of OH with the deliquesced NaCl was found to be much higher than under dry conditions due to pronounced segregation of  $\text{Cl}^-$  to the surface interface. We can therefore conclude that the presence of a  $\text{MgCl}_2$  component extracted to a sea-salt surface under subsaturated conditions will likely extend the reactivity of a sea-salt aerosol to lower relative humidity conditions increasing its contribution to  $\text{Cl}_2$  production in the marine boundary layer.

### 3.5. Summary

We have investigated the effect of relative humidity on OH uptake by surfaces of tropospheric importance, such as organic compounds, sea-salt components, and mineral dust. In order to surmount diffusion limitations resulting from the introduction of high water vapor, the flow tube setup incorporated three techniques: i) beads-packing, ii) parallel reactor tubes with a reference, and iii) surface dilution. The virtual cylindrical reactor approximation successfully quantified the reaction probability of OH for the surfaces of interest.

The OH exposure of the hydrophobic organic surfaces (paraffin wax, pyrene, and methane soot) did not result in a measurable change to their hydrophilicities.

However, water vapor was observed to enhance the OH reactivity on a glutaric acid surface, a hydrophilic organic compound. The humidity effect on OH uptake by sea salt and its components was dependent on the nature of the cation of the salts. A redistribution of surface ions under humid environments caused changes in the proton concentration on a surface, influencing the rate determining step in the reaction mechanism of OH uptake. The segregation effect, a derivative effect from the redistribution of ions, explains why the RH effect on OH uptake by sea salt is determined by  $\text{MgCl}_2$  rather than  $\text{NaCl}$ . Adsorbed water molecules on the surfaces of  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$  provide sites for OH radicals to react through the surface-catalyzed bimolecular reactions resulting in the enhancement of the OH reactivity to a mineral dust surface under wet conditions.

### Appendix 3-I. The Diffusion Coefficient of OH in a Mixture of Gases

The diffusion coefficient of OH in the flow of the mixture ( $D_c$ ) was determined based on equation 3.7.

$$D_c^{-1} = \sum_i \alpha_i \cdot D_{OH-i}^{-1} \quad (3.7)$$

where  $\alpha_i$  is the mixing ratio of the  $i^{\text{th}}$  flow, and  $D_{OH-i}$  is the diffusion coefficient of OH in the  $i^{\text{th}}$  flow. When  $W_{mix}$  and  $W_i$  are the flow rates of the mixture and  $i$ , respectively,  $\alpha_i$  was calculated as following:

$$\alpha_i = \frac{W_i}{W_{mix}} = \frac{W_i}{\sum_i W_i} \quad (3.40)$$

Under dry conditions, the mixed flow consists mainly of  $N_2$  and He with  $W_{N_2} = 1.75$  SLPM and  $W_{He} = 0.80$  SLPM, corresponding to  $\alpha_{N_2} = 0.686$  and  $\alpha_{He} = 0.314$ . Therefore,  $D_c$  was calculated as  $213 [\pm 17] \text{ cm}^2 \text{ Torr s}^{-1}$ .

The 50% RH condition generated the water vapor flow with  $W_{H_2O} = 0.30$  SLPM to the system, and adjusted the  $N_2$  flow to  $W_{N_2} = 1.45$  SLPM for a constant pressure. Under this condition, the mixing ratios were  $\alpha_{N_2} = 0.569$ ,  $\alpha_{He} = 0.314$ , and  $\alpha_{H_2O} = 0.118$ , with  $D_c = 215 [\pm 30] \text{ cm}^2 \text{ Torr s}^{-1}$ . 50% RH contributes only 1% of difference in the diffusion of OH in the flow.

## Appendix 3-II. The Relative Intensity of OH, $R_{surface}$

$[OH]_t$ , the concentration of OH at time  $t$ , is expressed as Equation 3.41 using Equation 3.1.

$$-\ln \frac{[OH]_t}{[OH]_0} = k_{obs} t \quad (3.1)$$

$$[OH]_t = [OH]_0 \cdot \exp(-k_{obs} \cdot t) \quad (3.41)$$

in turn,  $[OH]_{surface}$  and  $[OH]_{reference}$ , which are the concentrations of OH measured after exposure to the organic and inorganic surfaces of interest and the reference (halocarbon wax), respectively, are expressed as follows:

$$[OH]_{surface} = [OH]_0 \cdot \exp(-k_{obs}^{surface} \cdot t) \quad (3.42)$$

$$[OH]_{reference} = [OH]_0 \cdot \exp(-k_{obs}^{reference} \cdot t) \quad (3.43)$$

The relative intensity of OH for the heterogeneous reaction on the aerosol surface of interest,  $R_{OH}$ , is defined by Equation 3.13 as discussed in Section 3.3.2:

$$R_{OH} = \frac{[OH]_{Surface}}{[OH]_{reference}} = \frac{I_{Surface}^{OH}}{I_{reference}^{OH}} \quad (3.8)$$

where  $I_{surface}^{OH}$  and  $I_{reference}^{OH}$  are the signal intensities of OH in detection from the reactor and the reference, respectively. Using Equations 3.42 and 3.43,  $R_{OH}$  is related to the observed rate constants for each material as follows:

$$R_{OH} = \frac{[OH]_{Surface}}{[OH]_{reference}} = \frac{[OH]_0 \cdot \exp(-k_{obs}^{surface} \cdot t)}{[OH]_0 \cdot \exp(-k_{obs}^{reference} \cdot t)} \quad (3.44)$$

$$R_{OH} = \exp[-(k_{obs}^{surface} - k_{obs}^{reference}) \cdot t] \quad (3.9)$$

### Appendix 3-III. Determination of $\gamma_{OH}$ from $R_{surface}$

The following is an example of the determination of  $\gamma_{OH}$  on pure paraffin wax surface from  $R_{paraffin\ wax}$  using the following given values.

$$l_a = 2.6\text{ cm} = 2.6 \times 10^{-2}\text{ m}$$

$$r_a = 0.474\text{ cm} = 4.74 \times 10^{-3}\text{ m}$$

$$n = 60$$

$$r_b = 0.149\text{ cm} = 1.49 \times 10^{-3}\text{ m}$$

$$p = 100\text{ Torr}$$

$$T = 293\text{ K}$$

Therefore, the following may be calculated,

$$V = (\pi r_a^2 l_a) - \frac{4}{3} \pi r_b^3 n = 1.01 \times 10^{-6} m^3 \text{ (Equation 3.10),}$$

$$S = 4\pi r_b^2 n = 1.66 \times 10^{-3} m^2 \text{ (Equation 3.11)}$$

$$r_v = \frac{2V}{S} = 1.22 \times 10^{-3} m \text{ (Equation 3.12)}$$

$$l_v = \frac{V}{\pi r_v^2} = 2.16 \times 10^{-1} m \text{ (Equation 3.13)}$$

$$t_v = \frac{V}{W} = 3.13 \times 10^{-3} s \text{ (Equation 3.14)}$$

$$c_{OH} = 1.45 \times 10^2 \cdot \sqrt{\frac{T}{\mu_{OH}}} = 602 m \cdot s^{-1}$$

Since,  $D_c$  was calculated as  $213 [\pm 17] \text{ cm}^2 \text{ Torr s}^{-1}$  in Appendix 3-I,

$$k_{diff} = \frac{3.66 D_c}{r^2 P} = 528.8 s^{-1} \text{ (Equation 3.4).}$$

For halocarbon wax as a reference,  $\gamma_{OH} = 6 \times 10^{-4}$  [Bertram *et al.*, 2001], therefore,

$$k_{kin}^{halo} = \frac{\gamma_{OH}^{halo} \cdot c_{OH}}{2 \cdot r_v} = 148.3 s^{-1} \text{ and } k_{obs}^{halo} = \left( \frac{1}{k_{diff}} + \frac{1}{k_{kin}^{halo}} \right)^{-1} = 115 s^{-1}.$$

The upper limit of the relative intensity of OH for paraffin wax obtained experimentally was 0.297. Therefore,  $k_{obs}^{paraffin}$  for paraffin wax is calculated using Equation 3.9, followed by determining  $k_{kin}^{paraffin}$ .

$$k_{obs}^{paraffin} = k_{obs}^{reference} - \frac{\ln(R_{paraffin})}{t} = 503.3 s^{-1}$$

$$k_{kin}^{paraffin} = \left( \frac{1}{k_{obs}^{paraffin}} - \frac{1}{k_{diff}} \right)^{-1} = 1.04 \times 10^4 s^{-1}$$

Finally, the reaction probability of OH on paraffin wax is determined as follows:

$$\gamma_{OH}^{paraffin} = \frac{2r \cdot k_{kin}^{paraffin}}{c_{avg} + r \cdot k_{kin}^{paraffin}} = 0.041$$

The uncertainty of  $\gamma_{OH}$  is obtained from the upper and lower limits of  $R_{OH}$ , rather than from the error propagation described in Appendix 3-IV. For example, the lower limit of  $R_{OH}$  on paraffin wax is 0.265, which corresponds  $\gamma_{OH}^{paraffin} = 1$ . Therefore, the possible range of  $\gamma_{OH}^{paraffin}$  is 0.04 - 1.

## Appendix 3-IV. Errors in the VCR Approximation

### A. 3-IV. 1. The basic rules of error propagation

$$z = x \pm y, \quad \Delta z = \sqrt{(\Delta x)^2 + (\Delta y)^2} \quad (3.45)$$

$$z = x \cdot y, \quad \frac{\Delta z}{z} = \sqrt{\left(\frac{\Delta x}{x}\right)^2 + \left(\frac{\Delta y}{y}\right)^2} \quad (3.46)$$

$$z = x^m \cdot y^n, \quad \frac{\Delta z}{z} = \sqrt{\left(\frac{m \cdot \Delta x}{x}\right)^2 + \left(\frac{n \cdot \Delta y}{y}\right)^2} \quad (3.47)$$

$$z = f(x, y), \quad \Delta z = \left(\frac{\partial f}{\partial x}\right) \cdot \Delta x + \left(\frac{\partial f}{\partial y}\right) \cdot \Delta y \quad (3.48)$$

### A. 3-IV. 2. The Initial Errors in Measurements

$$\begin{aligned} l_a &= 2.6 [\pm 0.1] \text{ cm} & r_a &= 0.474 [\pm 0.005] \text{ cm} \\ r_b &= 0.149 [\pm 0.002] \text{ cm} & p &= 100 [\pm 1] \text{ Torr} \\ T &= 293 [\pm 1] \text{ K} & W &= 2.55 [\pm 0.04] \text{ SLPM.} \end{aligned}$$

### A. 3-IV. 3. Errors in $V$ , $S$ , $l_v$ , $r_v$ , and $t$

The volume of the space in which OH can freely move ( $V$ ) is the difference between  $V_{tube}$  and the total volume of the beads packed in a flow tube.

$$V = V_{tube} - V_{bead} \cdot n \quad (3.49)$$

where  $V_{tube}$  and  $V_{bead}$  are the volume of a tube and the volume of a bead, respectively.

Since  $V_{tube} = l_a \cdot \pi \cdot r_a^2$ , the propagated error in  $V_{tube}$  is

$$\frac{\Delta V_{tube}}{V_{tube}} = \sqrt{\left(\frac{\Delta l_a}{l_a}\right)^2 + \left(\frac{2\Delta r_a}{r_a}\right)^2} = \sqrt{\left(\frac{0.1}{2.6}\right)^2 + \left(\frac{0.01}{0.474}\right)^2} = 4\%$$

$$\text{For } V_{bead} = \frac{4}{3} \pi \cdot r_b^3, \quad \frac{\Delta V_{bead}}{V_{bead}} = \sqrt{\left(\frac{3\Delta r_b}{r_b}\right)^2} = \sqrt{\left(\frac{0.006}{0.149}\right)^2} = 4\%.$$

Therefore,  $\Delta V = \sqrt{(4\% \times V_{tube})^2 + (4\% \times V_{bead} \cdot n)^2} = 8.04 \times 10^{-8} m^3$ , since  $V_{tube} = 1.84 \times 10^{-6} m^3$  and  $V_{bead} = 1.37 \times 10^{-8} m^3$ . This corresponds 7% error in  $V$ .

$$\text{For } S, \quad \frac{\Delta S}{S} = \frac{\Delta r_b^2}{r_b^2}, \text{ as } S = 4\pi r_b^2 n. \quad \text{Therefore, } \frac{\Delta S}{S} = 3\%.$$

For  $l_v$ ,  $r_v$ , and  $t$ ,

$$\frac{\Delta l_v}{l_v} = \sqrt{\left(\frac{\Delta V}{V}\right)^2 + \left(\frac{\Delta S}{S}\right)^2} = 8\% \quad (\because l_v = \frac{V}{S}),$$

$$\frac{\Delta r_v}{r_v} = \sqrt{\left(\frac{\Delta V}{V}\right)^2 + \left(\frac{\Delta S}{S}\right)^2} = 8\% \quad (\because r_v = \frac{2V}{S}), \text{ and}$$

$$\frac{\Delta t}{t} = \sqrt{\left(\frac{\Delta V}{V}\right)^2 + \left(\frac{\Delta W}{W}\right)^2} = 7\% \quad (\because t = \frac{V}{W}).$$

#### A. 3-IV. 4. Errors in Diffusion Coefficients

The errors in the diffusion coefficients of OH in  $N_2$  and He in the mixtures are 5% and 12%, respectively [Bertram *et al.*, 2001; Ivanov *et al.*, 2007; Section 3.3.1]. Since the errors in the flow rates are 2%, the propagated error in the mixing ratio ( $\alpha_i$ ) is calculated to be 3%.

$$\text{For } D_c^{-1} = \alpha_{N_2} \cdot D_{OH-N_2}^{-1} + \alpha_{He} \cdot D_{OH-He}^{-1},$$

$$\frac{\Delta(\alpha_{N_2} \cdot D_{OH-N_2}^{-1})}{\alpha_{N_2} \cdot D_{OH-N_2}^{-1}} = \sqrt{\left(\frac{\Delta \alpha_{N_2}}{\alpha_{N_2}}\right)^2 + \left(\frac{\Delta(D_{OH-N_2}^{-1})}{D_{OH-N_2}^{-1}}\right)^2} = \sqrt{(0.03)^2 + (0.12)^2} = 12\%,$$

$$\text{and, } \frac{\Delta(\alpha_{He} \cdot D_{OH-He}^{-1})}{\alpha_{He} \cdot D_{OH-He}^{-1}} = \sqrt{(0.03)^2 + (0.05)^2} = 6\%. \quad \text{Therefore, } \frac{\Delta D_c}{D_c} = 11\%.$$

Since  $k_{diff} = \frac{3.66D_c}{r^2P}$ ,

$$\frac{\Delta k_{diff}}{k_{diff}} = \sqrt{\left(\frac{\Delta D_c}{D_c}\right)^2 + \left(\frac{2\Delta r_v}{r_v}\right)^2 + \left(\frac{\Delta P}{P}\right)^2} = \sqrt{(0.11)^2 + (2 \times 0.08)^2 + (0.01)^2} = 19\%$$

#### A. 3-IV. 5. Errors in Kinetics

The error in  $k_{kin}$  depends on the heterogeneous reactivity of OH to the surface material. Therefore, in the case of  $k_{kin}$  and  $\gamma_{OH}$ , only approximate estimations of the errors under certain assumptions are available.

Assuming that the errors in  $k_{kin}^{reference}$  are determined by the error in  $r_v = 8\%$ , the error in  $k_{obs}^{reference}$  is calculated to be 10% based on the additivity of kinetic resistances (Equation 3.3).

In the modified Equation 3.9,  $k_{obs}^{surface} = k_{obs}^{reference} - \frac{\ln(R_{surface})}{t}$ ,

$\Delta(\ln(R_{surface})) = \left(\frac{1}{R_{surface}}\right) \cdot \Delta R_{surface}$  is calculated to be 0.05 since the error in  $R_{surface}$  is

5%. Accounting for 7% error in  $t$ , the error in  $k_{obs}^{surface}$  is estimated to be 14% approximately at  $R_{surface} = 0.50 \pm 0.05$ .

Under the assumption  $\frac{\Delta k_{kin}^{surface}}{k_{kin}^{surface}} = \sqrt{\left(\frac{\Delta k_{obs}^{surface}}{k_{obs}^{surface}}\right)^2 + \left(\frac{\Delta k_{diff}}{k_{diff}}\right)^2}$ , the error in

$k_{kin}^{surface}$  is estimated as 24%. Errors in the OH reaction probability are calculated based on Equation 3.6.

$$\frac{\Delta \gamma_{OH}}{\gamma_{OH}} = \sqrt{\left(\frac{\Delta r_v}{r_v}\right)^2 + \left(\frac{\Delta k_{kin}^{surface}}{k_{kin}^{surface}}\right)^2} = \sqrt{(0.07)^2 + (0.24)^2} = 25\%$$

However, note that the uncertainties of  $\gamma_{OH}$  are obtained from the upper and lower limits of  $R_{OH}$ , but not from the error propagation described above in Appendix 3-III. In other words, only random errors in measurements were accounted. However, the uncertainty from error propagation can be used to determine how much change in  $\gamma_{OH}$  may be considered experimentally significant.

## Appendix 3-V. Determination of the fraction of OH-H<sub>2</sub>O complex

### A.3-V.1. $k_{3.16}$

The transition state in Reaction 3.16 could not be determined at a level of B3LYP and MP2 theory, implying the energy barrier is extremely shallow or zero. Therefore, the reaction is assumed to proceed whenever the reactants collide with each other with the proper orientation. The rate constant within the reactive hard-sphere model is calculated by the collision frequency ( $Z$ ) and the activation energy ( $E^*$ ) as follows [Steinfeld *et al.*, 1998] :

$$k = Z \cdot p \cdot e^{-E^* / k_B T} = \pi d^2 \left( \frac{8 k_B T}{\pi \mu} \right)^{1/2} p \cdot e^{-E^* / k_B T} \quad (3.50)$$

where

- $d$  : hard sphere minimum approach distance (m)
- $k_B$  : Boltzmann constant ( $1.381 \times 10^{-23}$  J K<sup>-1</sup>)
- $T$  : Temperature (298 K)
- $\mu$  : Reduced mass (kg)
- $p$  : Steric factor

The distance  $d$  was set as that between two oxygen atoms in the complex,  $d = 2.86 \times 10^{-10}$  m, because the centers of mass are close to the oxygen atoms in OH and H<sub>2</sub>O. Since no entrance barrier ( $E^* = 0$ ) was assumed, the rate constant was calculated as  $2.18 \times 10^{-16} p \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ . Therefore, the steric factor,  $p$ , is the last variable to be determined.

The steric factor  $p$  corresponds to the relative orientation of the reacting

molecules, a deviation of the reactive hard-sphere model from the observed gas-kinetic collision rate [Levine, 1990, Akins, 1990, Laidler *et al.*, 1992, Steinfeld *et. al.*, 1998]. Since the quantitative determination of  $p$  is beyond the scope of this thesis and the transition state was not optimized, an approximate value was estimated by scanning the potential energy surface through the variables in Figure 3.16.

**Figure 3.16.** Variables to scan the potential energy surface of OH-H<sub>2</sub>O complex.

**Figure 3.17.** The energy dependence on the orientation of the molecules. The dotted line is the total energy of the reactants.

$\varphi_H$  is the angle of the hydrogen atom in OH to the of two oxygen atoms representing the orientation of OH,  $\varphi_{OH}$  is the angle of OH to the plane consisting of H<sub>2</sub>O representing the orientation of H<sub>2</sub>O, and  $d_{O-O}$  is the distance between two oxygen with fixed O—H distance in OH. Although the energy dependence on  $\varphi_H$  and  $\varphi_{OH}$  did not cover the entire orientation of the two molecules, it provided an approximation for  $p$ .

The energy dependence on the angle variables for angles ( $\varphi_H$  (a) and  $\varphi_{OH}$  (b)) is shown in Figure 3.17.

According to Figure 3.17, most orientations were favorable for the reaction. When  $\varphi_H$  was in the range  $-90^\circ$  to  $120^\circ$ , the energy of the complex was below than that of the reactants, implying 60% of OH orientation is favorable for the reaction. In the case of  $\varphi_{OH}$ , 80 % is proper for the reaction. Therefore,  $p$  is roughly estimated as 0.5 giving  $k_{3.16} = 1.1 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ .

#### A.3-V.2. $k_{3.16}^{-1}$

For the reverse of Reaction 3.16, self-dissociation of OH-H<sub>2</sub>O, a loose complex of OH and H<sub>2</sub>O (OH $\cdots$ H<sub>2</sub>O in Table 3.1) was assumed to represent the transition state in the reaction although no optimized transition state was found. The structures of OH and H<sub>2</sub>O at their individual global minima were retained in the loose complex while the distance between them was long enough not to interrupt the stability of each species. Figure 3.18 shows how the total energy of the complex depends on  $d_{O-O}$ . Since the energy started converging at the distance of 5.5 Å,  $d_{O-O}$  was set at 5.5 Å.

**Figure 3.18.** The energy dependence on  $d_{O-O}$  in the OH $\cdots$ H<sub>2</sub>O complex.

The rate constant for the reverse reaction,  $k_{3.16}^{-1}$ , was determined using the loose

complex (OH $\cdots$ H<sub>2</sub>O) and OH-H<sub>2</sub>O complex through the Eyring equation [Atkins, 1990; Laidler *et al.*, 1995].

$$k = \frac{k_B T}{h} e^{\Delta^* S^\circ / R} e^{-\Delta^* H^\circ / RT} = \frac{k_B T}{h} e^{\Delta^* G^\circ / RT} \quad (3.51)$$

where

- $h$  : Planck's constant ( $6.626 \times 10^{-34}$  J s)
- $R$  : Gas constant ( $8.315$  J K<sup>-1</sup> mol<sup>-1</sup>)
- $\Delta^* S^\circ$  : Entropy change between a reactant and a transition state
- $\Delta^* H^\circ$  : Enthalpy change between a reactant and a transition state
- $\Delta^* G^\circ$  : Gibbs free energy change between a reactant and a transition state.

The Gibbs free energies of the two complexes (Table 3.1) gave a rate constant  $k_{3.16}^{-1} = 5.3 \times 10^9$  s<sup>-1</sup> at 298 K. Since this reaction is first order, the lifetime of the complex could be determined as the inverse of the rate constant, or  $1.9 \times 10^{-10}$  s.

### A.3-V.3. Fraction of a OH-H<sub>2</sub>O complex in the Gas-phase

Using Equation 3.21 and the rate constants obtained above, the equilibrium constant was determined as follows:

$$K_{3.15} = \frac{k_{3.15}}{k_{3.15}^{-1}} = \frac{1.1 \times 10^{-16} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}}{5.3 \times 10^9 \text{ s}^{-1}} = 2.1 \times 10^{-26} \text{ cm}^3 \text{ molecule}^{-1}.$$

Since the concentrations of OH and H<sub>2</sub>O are  $8 \times 10^{11}$  molecule cm<sup>-3</sup> and  $3.2 \times 10^{17}$  molecule cm<sup>-3</sup>, respectively, at 40% RH, the concentration of OH-H<sub>2</sub>O complex was calculated as follows:

$$[OH - H_2O] = K_{3.15} \cdot [OH] \cdot [H_2O] = 5.3 \times 10^2 \text{ molecule cm}^{-3}$$

Therefore, the fraction of OH-H<sub>2</sub>O complex in the gas phase was estimated at  $6.6 \times 10^{-10}$ .

## Appendix 3-VI. Determination of $\gamma_{OH}$ on the pure organic surfaces from $R_{surface}$ for diluted surfaces

### A.3-VI.1. The material with known $\gamma_{OH}$ (Pyrene as an example)

$R_{surface} = 0.571$  was measured on a diluted pyrene surface under dry conditions, which corresponds to  $\gamma_{OH} = 0.0027$  (See Appendix 3-II). As the reaction probability of OH on pyrene was known to be 0.30 [Bertram *et. al.*, 2001], the fraction of pyrene in the diluted mixture, denoted  $\beta_{pyrene}$ , was determined as follows with Equation 3.15:

$$\gamma_{OH}^{mix} = \sum_j \beta_j \gamma_{OH}^j = \beta_{pyrene} \gamma_{OH}^{pyrene} + (1 - \beta_{pyrene}) \gamma_{OH}^{reference} \quad (3.15)$$

$$\beta_{pyrene} = \frac{\gamma_{OH}^{mix} - \gamma_{OH}^{reference}}{\gamma_{OH}^{pyrene} - \gamma_{OH}^{reference}} = 0.0070 \quad (3.52)$$

Since  $\beta_{pyrene}$  is independent of dry or wet conditions, it was possible to retrieve the  $\gamma_{OH}^{mix}$  under wet conditions for the pure pyrene surface ( $\gamma_{OH}^{pyrene}$ ) using the same value of  $\beta_{pyrene}$  according to Equation 3.53:

$$\gamma_{OH}^{pyrene} = \frac{\gamma_{OH}^{mix} - (1 - \beta_{pyrene}) \gamma_{OH}^{reference}}{\beta_{pyrene}} \quad (3.53)$$

### A.3-VI.2. The material on unknown $\gamma_{OH}$ (Glutaric acid as an example)

Since  $\gamma_{OH}$  on glutaric acid was unknown,  $R_{OH}$  on pure glutaric acid was first measured under dry conditions. Based on the obtained  $R_{OH}$  we were able to estimate  $\gamma_{OH}$  of 0.24 for glutaric acid following the procedure described in the Section A.3-VI.1.

### Appendix 3-VII. Reaction Mechanism of OH Uptake by NaCl

Keene *et al.* [1993], Oum *et al.* [1998] and Finalyson-Pitts *et al.* [2000] suggested the following reaction mechanism of OH uptake by NaCl:

Reaction 3.28 is assumed to be the rate-determining step. At a high pH, i.e. low  $[\text{H}^+]$ , the dissociation of  $\text{HOCl}^-$  in Reaction 3.27 is faster than Reaction 3.28, such that the reaction mechanism is pH sensitive.

## **Chapter 4**

# **Release of $\text{Cl}_2$ from NaCl upon OH Uptake**

## 4 1. Introduction

Atomic chlorine (Cl) is an extremely powerful oxidant with 1-2 orders of magnitude higher reactivity than OH [DeMore *et al.*, 1997]. For its higher reactivity, Cl is an important species in chemistry of the marine boundary layer and the coastal urban areas. Although the Cl mixing ratio of  $1.3 \times 10^5$  atoms  $\text{cm}^{-3}$  in coastal area [Spicer *et al.*, 1998] is smaller than that of OH, oxidation of atmospheric trace species by Cl can occur at substantially faster rates. Besides its reaction with ozone in the stratosphere (Reaction 4.1) [Molina *et al.*, 1974], Cl can influence acidity (Reaction 4.2), oxidize various volatile organic compounds (Reaction 4.2), and perturb the ozone balance in the troposphere (Reactions 4.2 - 4.8) [Singh *et al.*, 1988; DeHaan *et al.*, 1999; Seinfeld *et al.*, 1998; Pechtl *et al.*, 2007]. Examples of Cl reactions important in the troposphere include the following:

The alkyl radical ( $\text{R}\cdot$ ) produced in Reaction 4.2 may further participate in  $\text{HO}_x$  and  $\text{NO}_x$  radical cycling, important in photochemical pollution formation:

Sources of atomic chlorine (Cl) in the troposphere include (i) the gas-phase reaction of OH with HCl [Singh *et al.*, 1988], (ii) the photodissociation of chlorine

monoxide (ClO), and (iii) the photodissociation of molecular chlorine (Cl<sub>2</sub>):

The mixing ratio of Cl<sub>2</sub> was measured in the marine boundary layer to be ~150 ppt [Spicer *et al.*, 1998]. This concentration exceeds predictions based on a mechanism for autocatalytic heterogeneous reactions of HOCl on sea salt aerosol and subsequent oxidation of Cl<sup>-</sup> ions [Sander *et al.*, 1996; Vogt *et al.*, 1996], suggesting an additional, yet unrecognized Cl<sub>2</sub> source.

Another possible source for Cl radicals is the OH heterogeneous reaction with a deliquesced NaCl surface [Keene *et al.*, 1993; Oum *et al.*, 1998; Knipping *et al.*, 2000; 2002] (see Appendix 3-VII). This reaction can be also responsible for the chloride deficit (the low Cl/Na ratio) observed in sea-salt particles [Junge, 1956; Cicerone, 1981; Keene *et al.*, 1990; Mouri *et al.*, 1993; McInnes *et al.*, 1994] (see Section 1.5.2). Such mechanism may also explain release of Cl<sub>2</sub> from NaCl upon OH uptake. However, it is restricted to high relative humidity conditions, greater than the deliquescence RH of NaCl, characteristic of the lower troposphere.

The upper troposphere is rather under arid conditions, which would more likely enable such a OH<sub>(g)</sub> + NaCl<sub>(s)</sub> heterogeneous mechanism. For example, the content of water vapor at altitudes ~5 km is limited to about 0.7 Torr of H<sub>2</sub>O [Seinfeld and Pandis, 1998].

In addition, the vertical distribution of sea-salt aerosol shows an exponential decrease, which establishes a fairly constant profile above 900 m in the marine boundary layer [Gras, 1991; Jaenicke, 1993]. This indicates that approximately 5% of sea-salt aerosols still exist at higher altitudes in the troposphere. Furthermore, formation of Cl<sub>2</sub> in the upper troposphere would have important implications for Cl<sub>2</sub>

dissociation in the presence of intense solar radiation at high altitudes.

In this chapter, a product study for the OH heterogeneous reaction with NaCl under dry to low relative humidity conditions is described. Since NaCl is the major component of sea salt, it is important to determine the net OH uptake on NaCl under various conditions relevant to the troposphere. This study provides experimental data essential to determining a mechanism for Cl<sub>2</sub> release from the OH reaction with sea salt at high altitude under arid conditions.

## 4. 2. Experimental

The experimental setup used was described previously in Chapters 2 and 3. Two differences should be noted: (i) an increased number of beads used to pack the reactor tubes (80 instead of 60), and (ii) no pre-pumping before the CI region. Both changes were made to increase the sensitivity to detection of gas-phase products, expected in relatively low concentrations. In particular, (ii) enabled all species in the flow tube to proceed to the CI region without any loss due to pumping, which was required under high relative humidity conditions (see Chapter 3) to minimize water interference (formation of water clusters) by preventing large amount of water molecules being introduced to the CI region.

To minimize possible secondary reactions by O<sub>2</sub> and HO<sub>2</sub>, the H + NO<sub>2</sub> reaction was used for OH production. The CIMS sensitivity to OH was  $4.2 [\pm 0.3] \times 10^7$  molecule cm<sup>-3</sup> cps<sup>-1</sup> under the dry condition, while it decreased by one order of magnitude under wet conditions (Section 2.2)

Instead of a halocarbon wax coating (termed ‘the halocarbon wax reference’), bare glass beads without any coating were used in the reference tube (termed ‘the glass

reference') to reduce the chlorine background observed from the OH + halocarbon wax reaction (see Section 4.3). Preparation of NaCl surfaces was done as described in Section 3.2.3.

X-ray photoelectron spectroscopy (XPS) was used to study the reaction products formed on a solid salt surface exposed to OH. Na(1s) spectra were analyzed offline by XPS with the Mg anode photon energy of 1253.6 eV and the incident angle of 10°. For NaCl deposition, a silicon wafer of 1×1 cm was dipped into a supersaturated NaCl solution and dried in an oven (~100 °C).

Experimental results were simulated using ChemKin to elucidate the reaction mechanism of Cl<sub>2</sub> formation.

### 4. 3. Results

Mass spectra of the gas-phase products produced in a reactor flow tube packed with beads coated with NaCl (termed 'the reactor spectrum') were compared with reference spectra to determine which masses correspond to reaction products. Use of the parallel reactors enables identification and canceling out the background masses potentially arising from other OH heterogeneous reactions in the flow system. For example, although halocarbon wax (used for reactor wall deactivation) is essentially inert to OH reaction, the reaction probability is nonzero, reported at  $6 \times 10^{-4}$  [Bertram *et al.*, 2001]. We observed efficient Cl<sub>2</sub> production from halocarbon wax upon OH uptake as described later in this section.

Throughout the mass range of  $m/z = 5$  amu (atomic mass units) to 170 amu, peaks at  $m/z$  55 and 162 showed noticeable differences when the total flow was switched from the reaction tube to the reference tube, shown in Figure 4.1.

**Figure 4.1.** Mass spectra from the reactor and the halocarbon wax reference

These masses were assigned to  $\text{HClF}^-$  (55 amu) and  $\text{SF}_5\text{Cl}^-$  (162 amu), which are likely the ion products of the electron transfer from  $\text{SF}_6^-$  to  $\text{HCl}$  [Huey *et al.*, 1995] according to the following reactions:

with  $k_{4.11} = 1.5 [\pm 30\%] \times 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  and  $k_{4.12} = 0.42 [\pm 30\%] \times 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Streit, 1982]. The branching ratios for Reactions 4.10, 4.11, and 4.12 are 23%, 44%, and 33%, respectively [Streit, 1982]. The peaks at masses of 57, and 164 amu, corresponding to the Cl isotope ( $^{37}\text{Cl}$ ), are also shown in Figure 4.2 with  $I_{57\text{amu}}/I_{55\text{amu}} = 0.31$  and  $I_{164\text{amu}}/I_{162\text{amu}} = 0.39$ .

To remove the possible Cl contribution from the reference, bare glass beads

were used in place of the halocarbon wax coated beads. Figure 4.2 shows a decrease in the peak at 55 amu in the glass reference spectrum compared to that in the halocarbon wax reference spectrum.

The relative ratios of the intensities of the peak at 55 amu in the spectra was 1 : 0.83 : 0.63 (NaCl : Halocarbon wax : Glass). Therefore, 37% of the intensity of the peak in the NaCl reactor spectrum (Figure 4.1) was attributed to the OH heterogeneous reaction on NaCl.

**Figure 4.2.** Comparison of the halocarbon waxed reference spectrum with the glass reference spectrum

The HCl signal ( $m/z = 55$ ) was calibrated using known amounts of  $\text{Cl}_2$  as follows:

Since Reaction 4.13 is fast ( $k_{4.13} = 2.0 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Berho *et al.*, 1999]) and irreversible ( $k_{-4.13} = 4.18 \times 10^{-42} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Baulch *et al.*, 1981]), in excess H,

$\text{Cl}_2$  transforms completely to HCl. HCl loss on NaCl surface was neglected since the reaction probability is relatively small ( $\gamma_{\text{HCl}}^{\text{NaCl}} = 3 \times 10^{-2}$ , [Fenter et al., 1994]) and the reaction time for producing HCl through Reaction 4.13 ( $\sim 10$  ms) is longer than the residence time in the beads-packing ( $\sim 4$  ms). The CIMS sensitivity to HCl was found to be  $3.7 \times 10^7$  molecule  $\text{cm}^{-3}$   $\text{cps}^{-1}$ .

A HCl ( $m/z = 55$ ) signal was linearly dependent on the OH concentration both under dry and 6% RH conditions as shown in Figure 4.3. Assuming that formation of HCl is solely due the title reaction, the yield of HCl per OH was calculated to be  $0.020 \pm 0.002$  under dry conditions and  $0.022 \pm 0.002$  at 6% of RH. Accounting for the measured OH reaction probability of  $\gamma_{\text{OH}} = 0.045 \pm 0.004$  on NaCl (see Section 3.3.6), the observed HCl was attributed to approximately half of OH uptake by NaCl.

**Figure 4.3.** Dependence of [HCl] ( $m/z = 55$ ) on [OH] under the dry conditions (■) and 6% RH (○).

As seen from Figure 4.4, the dependence of  $[\text{HCl}]$  on RH is non-monotonic. The initial small change in RH ( $0\% \rightarrow 2\%$  RH) was unfavorable for the production of HCl, whereas the production of HCl increased with further increases in RH up to 9%.

**Figure 4.4.** Dependence of  $[\text{HCl}]$  on RH

XPS spectra recorded for three NaCl samples were analyzed for changes in the Na(1s) signal, shown in Figure 4.5. In the figure, the samples were exposed to OH for 4 hours under dry and wet conditions: dry (thick solid line), 10% RH (thin solid line), and 80% RH (dashed line). For calibration, the blank spectra of NaCl (unexposed to OH), and NaOH are also shown. Compared to the unreacted NaCl, all three exposed samples show a shift of 0.4 eV in Na(1s) toward to that of NaOH. However, we were unable to see the shift dependence of Na(1s) on RH.

The observed Cl/Na ratios in the exposed samples obtained from XPS

measurements are listed in Table 4.1, showing that the OH exposure normally decreases the amount of surface chlorine. Moreover, the observed chlorine deficit was found to be even greater when the samples were exposed to OH under wet conditions. A significant chlorine deficit was observed when RH reached the values of higher than the deliquescence RH of NaCl (77%).

**Figure 4.5.** XPS spectra of Na(1s) for NaCl exposed to OH under different RH conditions: dry (thick solid line), 10% RH (thin solid line), and 80% RH (dotted line). Spectra for blank NaCl (unexposed to OH, dashed line) and NaOH (dash-dotted line) are shown for comparison.

**Table 4.1.** Cl/Na ratio for the unreacted and OH-exposed NaCl samples

RH	Blank	0%	10%	80%
Cl/Na	0.7470	0.7395	0.7366	0.6744

Although the possible peaks at  $m/z = 35$  and  $37$  corresponding to atomic Cl

were observed at a trace level, the peak intensities were smaller than the same masses in the halocarbon wax reference spectrum, shown in Figure 4.6. This indicates that the species corresponding to the peaks were not only the products of the heterogeneous reaction, but also the products of gas phase reactions. One possible species to be assigned for 35 amu is  $\text{OH}(\text{H}_2\text{O})$  produced from the gas phase reaction of  $\text{OH}^\cdot$  with  $\text{H}_2\text{O}$  likely introduced by a very small leak from ambient air (see Section 3.3.4.2.). The trace amount of  $\text{H}_2\text{O}$  is likely also responsible for the peak at 37 amu, assigned to  $\text{F}(\text{H}_2\text{O})$  from the reaction between  $\text{SF}_6^-$  and  $\text{H}_2\text{O}$  [Arnold *et al.*, 2001]. This is confirmed by the ratio of 37 to 35 amu ( $I_{37\text{amu}}/I_{35\text{amu}}$ ). The intensity of the peak at 37 amu was 23% of the peak at 35 amu, which is smaller than the natural abundance of  $^{37}\text{Cl}$  (32.6%).

**Figure 4.6.** The observed peaks at  $m/z = 35$  and 37.

The peaks at 52 and 70 amu corresponding to  $\text{HOCl}$  and  $\text{Cl}_2$ , respectively, were not observed within detection limit.  $\text{HOCl}$  can be detected as  $\text{HOClF}^-$  ( $m/z = 71$ ) by

the reaction with  $\text{SF}_6^-$  in the CI region. Although a peak at 71 amu was observed only under wet conditions, it is believed to correspond to  $\text{OH}^-(\text{H}_2\text{O})_3$ . Therefore it was not possible to separate the two likely contributions to  $m/z = 71$ .

The spectrum for the reaction of OH on a sea salt surface was identical to that on NaCl within experimental uncertainty. Evidence of bromine (or iodine)-containing species (other components of sea salt) was not observed.

## 4. 4. Discussion

### 4. 4. 1. Reactions in the Flow System

Considering that many gas-phase species from the radical source and reactions coexisted in the flow tube system, the chemistry involved may be described by a complex set of reactions rather than a simple heterogeneous reaction between OH and the NaCl surface. The possible reactions include the following:

*(R1) The heterogeneous reaction of OH with NaCl - The titled reaction*

*(R2) The heterogeneous reaction of unreacted gas-phase sources for OH generation on NaCl – The unreacted gas-phase sources including  $\text{H}_2$ ,  $\text{H}$ ,  $\text{NO}_2$  ( $\text{H}+\text{NO}_2$  scheme),  $\text{O}_2$  ( $\text{H}+\text{O}_2+\text{M}$  scheme), and  $\text{O}$  (from impurities described below).*

*(R3) The gas-phase reactions of OH with the species in (R2) – The secondary reaction of OH*

*(R4) All other gas-phase reactions involving the product of the title reaction*

According to our kinetics simulation (ChemKin) with the reaction for OH

production (Reaction 2.2) and two secondary reactions of OH (Reactions 2.5 and 2.6), ~84% of H ( $4.2 \times 10^{12}$  molecule  $\text{cm}^{-3}$ ) was estimated to survive in order to reach the NaCl surface. Atomic O was produced from the dissociation of a ppm impurity of  $\text{O}_2$  introduced with the He flow (as carrier flow for  $\text{H}_2$ ) through the microwave discharge cavity. Atomic O reacts with vibrationally excited  $\text{H}_2$  to produce H and OH [Han *et al.*, 2000; Balakrishnan, 2004].

where  $\text{H}_2^*$  is vibrationally excited  $\text{H}_2$  produced in the microwave discharge cavity.

Preliminary experiments showed that the heterogeneous uptake of  $\text{H}_2$ ,  $\text{NO}_2$ ,  $\text{O}_2$ , and O on NaCl were negligible compared to the OH uptake. However, the heterogeneous reaction of H was difficult to be distinguished since a small amount of OH was typically produced upon passing  $\text{H}_2$  through a microwave cavity due to ppm impurities in the He carrier gas (Reaction 4.14). A background study was done to explore the contribution of H to the heterogeneous reaction on NaCl as shown in Figure 4.7. The background OH was produced from the reaction between  $\text{H}_2^*$  and O in absence of  $\text{NO}_2$ . The efficiencies of H production in the microwave discharge and the OH production by Reaction 4.14 were dependent on the flow rate of the He carrier gas. As the flow rate of He increased, the production of H was linearly enhanced while OH reached a maximum and then decreased. HCl followed OH, not H, indicating the negligible contribution of H in the heterogeneous reaction. Therefore, OH was the only species available to react with NaCl to a significant extent.

The secondary reaction of OH (R3) was reduced by controlling the initial concentrations of the reactants, H and  $\text{NO}_2$  (or H and  $\text{O}_2$  in the case of the  $\text{NO}_x$ -free OH production source). Within the lifetime of OH,  $t = 45$  ms from production to detection,

only approximately 2.5% of OH (upper limit) was estimated to be consumed for the self-recombination (Reaction 2.5) under the usual condition of radical production. In fact, the loss of OH by secondary reactions was negligible unless the initial concentration of  $\text{NO}_2$  did not exceed  $1.5 \times 10^{12} \text{ molecule cm}^{-3}$  as seen in Figure 2.2 (see Chapter 2).

Although *R2* and *R3* may therefore be excluded, other interfering reactions (*R4*) must be identified in order to verify the reaction product(s).

**Figure 4.7.** Dependence of H, OH and HCl on He flow

#### 4.4.2. Verification of the Product of the Title Reaction

Although  $\text{Cl}_2$  was not directly detected and only HCl was observed at  $m/z = 55$  and 162, it is still under question whether HCl is the gas-phase product of the titled reaction, due to the possibility of interference of gas-phase reactions as *R4*. A potential

reaction and interfering source of chlorine-containing species is Reaction 4.13, which transforms Cl<sub>2</sub> into HCl in the presence of H at an extremely fast rate. Preliminary experiments for reproducibility of Reaction 4.13 in our system are described in Appendix 4-1. Since the reaction for OH production proceeded with excess H, most H ( $\sim 4 \times 10^{12}$  molecule cm<sup>-3</sup>) remained unreacted when the flow reached a NaCl surface. Therefore, there was a reasonable possibility that Reaction 4.13 took place if Cl<sub>2</sub> was released from the NaCl surface.

In contrast, Reaction 4.13 could be inhibited by introducing O<sub>3</sub>, which removes H with an extremely fast rate ( $k_{4.15} = 2.95 \times 10^{-11}$  cm<sup>3</sup> molecule<sup>-1</sup> s<sup>-1</sup> [Yu *et al.*, 1997]):

Kinetics modeling was performed to predict the gas phase chlorine-containing products from the titled reaction. The model was designed to investigate how added O<sub>3</sub> can inhibit the transformation of Cl<sub>2</sub> into HCl (Reaction 4.13). The reactions included in the model and the initial experimental concentrations of species are listed in Table 4.2 and Table 4.3, respectively. The initial concentrations of HCl and Cl<sub>2</sub> were determined based on two assumptions: A major product of the title reaction is likely HCl (*Assumption 1*) or Cl<sub>2</sub> (*Assumption 2*). Figure 4.8 shows the HCl concentration predicted based on *Assumption 1* ( $\triangle$ ) and *Assumption 2* ( $\circ$ ), as well as the experimentally measured HCl concentration ( $\blacksquare$ ). The measured [HCl] agreed well with *Assumption 2*, providing support that Cl<sub>2</sub> is the gas-phase product of the titled reaction.

**Table 4.2.** The reactions included the kinetic model used in the present study.

No.	Reaction	$k$ (cm <sup>3</sup> molecule <sup>-1</sup> s <sup>-1</sup> )	Reference
2.2	$\text{H} + \text{NO}_2 \rightarrow \text{OH} + \text{NO}$	$1.3 \times 10^{-10}$	DeMore, 1997

H <sub>2</sub>		$9.0 \times 10^{13}$

**Figure 4.8.** The [HCl] dependence on [O<sub>3</sub>]

The chance of the transformation of atomic chlorine was negligible since the possible reaction (Reaction 4.25) is slow ( $k_{4.25} = 1.77 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Atkinson *et al.*, 2001]) and irreversible ( $k_{4.25}^{-1} = 7.48 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Allison *et al.*, 1996]). Only less than 1% of Cl could participate in this reaction even though

the high concentration of H<sub>2</sub> is taken into account.

Upon OH exposure the shift of Na(1s) toward NaOH (Figure 4.5) implies that the title reaction causes substitution of Cl with OH or O in the lattice. Assuming that NaOH is the oxidized form of Na by OH uptake, the amount of oxidation by OH for 4 hours was estimated at 35% from the superposition of the XPS spectrum for NaOH and the unreacted NaCl basis set.

#### 4.4.3. The Effect of RH and the Proposed Reaction Mechanism

The increase in the chlorine deficit (Table 4.1) and the yield of HCl upon OH uptake (Figure 4.4) under wet conditions indicates that Cl<sub>2</sub> release to the gas phase is enhanced by water adsorption. However, the observation described in Chapter 3 showed no significant water effect on OH uptake by NaCl in the range of 0 to 48% RH. This further indicates that OH loss on NaCl is independent of RH within experimental error. These contradictory phenomena imply that the uptake of OH on NaCl occurs through at least two mechanisms including the one responsible for the Cl<sub>2</sub> release.

Other mechanisms may not involve any chlorine-containing species, but produce H<sub>2</sub>O or H<sub>2</sub>O<sub>2</sub> through surface-catalyzed bimolecular reactions [Steinfeld *et al.*, 1998] even though H<sub>2</sub>O<sub>2</sub> was not observed within detection limits (see Section 3.3.6.2). In case that H<sub>2</sub>O or H<sub>2</sub>O<sub>2</sub> production follows the Langmuir-Hinshelwood (L-H) mechanism, water adsorption would reduce the rate of product formation since the occupation of the active site by water decreases the probability for adsorbed OH to meet an adjacent OH ( $k_{3,35}$  in Section 3.3.6.2). Moreover, water adsorption reduces the number of active sites available for OH uptake, resulting in a decrease in the number of

sites available for radical uptake [Remorov *et al.*, 2002], which also influences the release of  $\text{Cl}_2$  as described later of this section.

In summary, the possible fates of adsorbed OH radicals on the active sites of NaCl are (i) desorbing to the gas-phase (no uptake), (ii) generating  $\text{Cl}_2$ , and (iii) generating other species. As RH increases, (ii) is enhanced (described further below), while (iii) is inhibited as described above so that the net uptake of OH does not change to a significant extent.

**Figure 4.9.** The Schematic of ionic transport in crystalline solids [West, 1984]

Returning to  $\text{Cl}_2$  release (ii), a potential reaction mechanism is initiation by OH uptake on surface  $\text{Cl}^-$  active sites (formation of  $\text{OH-Cl}^-$ ) followed by reaction with another  $\text{Cl}^-$  moved by ionic transport. The transport of ions is possible only when the vibrational energy of the bond is greater than the activation energy ( $E^*$ ) described in Figure 4.9 or via tunneling. Therefore, the probability of ionic transport between sites is proportional to  $\exp(-E^*/kT)$  where  $E^*$  is the activation energy,  $k$  is the Boltzmann

constant, and  $T$  is the temperature, following the Arrhenius equation [West, 1984]. Although  $E^*$  of NaCl is not well defined, the lattice vibration of NaCl ( $164\text{ cm}^{-1}$  [West, 1984]) suggests that only a small population has energy greater than  $E^*$  at room temperature. In this case, the step involving ionic transport heavily influences the net reaction rate.

Water adsorption likely lowers  $E^*$  by perturbing ionic bonds, which results in an enhancement of ionic transport in the crystalline lattice. This is consistent with a previous observation by Hemminger [1999] showing that even very low vapor pressure of water ( $\sim 2\%$  RH) enhanced the surface ionic mobility. As a consequence, the  $\text{Cl}_2$  release is expected to increase under wet conditions.

In contrast, the adsorption of water likely reduces the number of available sites for OH uptake as described in the early of this section. This effect competes with the positive effect of water described above with respect to the production of  $\text{Cl}_2$ . As seen in Figure 4.4, this screening effect of water caused the decrease in HCl when RH was increased from 0 to 2%, before the ionic mobility was enhanced. However,  $\text{Cl}_2$  production recovered at RH = 6% and increased further in comparison to dry conditions due to the effective assistance of water for the enhancement of ionic mobility.

Since measurements were not made at RH > 9% due to the restriction of water to CIMS sensitivity for OH detection, it is not clear how the water affects the production of  $\text{Cl}_2$  at high RH. Nevertheless, it is expected that the enhancement of the  $\text{Cl}_2$  production converges to a certain maximum because the negative effect of water by screening available sites for OH adsorption is proportional to RH, whereas the extent of enhancement of ionic mobility becomes smaller as RH increases [Hemminger, 1999]. This is consistent with the observation by Oum *et al.* [1998], who observed formation of

Cl<sub>2</sub> only after the deliquescence RH of NaCl, indicating a sharp increase in the production rate of Cl<sub>2</sub> at this RH. In fact, a yield of HCl per OH was found to be 0.036 at RH = 9%, which is already close to the reaction probability of OH on NaCl ( $\gamma_{OH}^{NaCl} = 0.045 [\pm 0.004]$ , see Chapter 3). Unless a catalytic mechanism is involved, the yield is not able to exceed this value.

#### 4. 4. Summary

Mass spectra of the gas-phase species produced from the OH heterogeneous reaction with NaCl were obtained to characterize the reaction products and the kinetics mechanism. Although only peaks corresponding to HCl were observed, an applied kinetics model, and reactivity experiments with O<sub>3</sub> verified that Cl<sub>2</sub>, a sole product of the heterogeneous reaction, transformed to HCl in the presence of H atoms. A Cl<sub>2</sub> yield per OH was determined to be  $0.020 \pm 0.002$  and  $0.022 \pm 0.002$  at 0 and 6% of RH, respectively. XPS characterization of the reacted NaCl surfaces showed a chlorine deficit by OH uptake, enhanced under wet conditions.

Enhancement in Cl<sub>2</sub> production was observed under wet conditions consistent with the measurement of the chlorine deficit in NaCl. Two reaction mechanisms were suggested to describe OH uptake by NaCl, including Cl<sub>2</sub> production.

#### Appendix 4-I. Transformation of Cl<sub>2</sub> into HCl in presence of H Atoms

Cl<sub>2</sub> reacts with H atoms to form HCl with the rate ( $k_{4.13} = 2.0 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Berho *et al.*, 1999]), while the reverse reaction is extremely slow ( $k_{4.13}^{-1} = 4.18 \times 10^{-42} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Baulch *et al.*, 1981]).

To verify the reproducibility of Reaction 4.13 in our system, a pure Cl<sub>2</sub> flow [99%, Matheson Tri Gas] was introduced with H<sub>2</sub> along with carrier gas flows of He and N<sub>2</sub> only. Masses corresponding to HCl ( $m/z = 55, 162$ ) were not observed until H was produced upon ignition of the microwave discharge. The concentration of H was assumed to be proportional to the concentration of H<sub>2</sub> passing through the microwave discharge. Reaction 4.13 was reproduced in our system as shown in Figure 4.10 (a). In addition, the inhibition of Reaction 4.13 by Reaction 4.15 was also checked by introducing O<sub>3</sub>. As more O<sub>3</sub> was introduced, the production of HCl from Cl<sub>2</sub> was reduced since more H was removed as seen in Figure 4.10 (b).

with  $k_{4.15} = 2.95 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$  [Yu *et al.*, 1997].

**Figure 4.10.** Anticorrelation between HCl (■) and Cl<sub>2</sub> (○) as H increases (a) and H decreases (b) in the presence of O<sub>3</sub>

## **Chapter 5**

# **Conclusions**

Controlling experimental conditions by targeting specific reactions enables simulation of the atmosphere under laboratory conditions, which provides fundamental knowledge about atmospheric chemistry. However, the deviation of these restricted conditions from reality carries limitations to explaining current phenomena in the atmosphere. This thesis focused on expanding the current state of knowledge for general application to the real atmosphere, particularly the troposphere.

Regarding the humidity, some part of the atmosphere is abundant in water vapor, whereas another part is arid. Information about the heterogeneous chemistry of gas-phase radicals on aerosols has been limited to specific reactions. One example is knowledge about the reaction probabilities of OH on the surfaces of tropospheric importance, which previous laboratory studies report only under dry conditions. In contrast, product studies have only been done under the extremely humid conditions. Therefore, heterogeneous chemistry of OH under complementary conditions was required to investigate the mechanism for application to the real troposphere.

Firstly, the effect of relative humidity on the OH uptake by organic and inorganic surfaces of tropospheric importance has been investigated. Due to diffusion limited conditions coming from introducing high water vapor, the flow tube setup was employed with three techniques: i) beads-packing, ii) parallel reactors with a reference, and iii) surface dilution. The virtual cylindrical reactor approximation successfully quantified the reaction probability of OH for the surfaces of interest. The effects were different depending on the characteristics of the aerosols. Hydrophobic organic aerosols were not influenced by the relative humidity for the uptake of OH radicals, whereas the presence of water vapor assisted uptake of OH on glutaric acid, a hydrophilic organic aerosol. Inorganic surfaces exhibited different behavior under wet

conditions. Only hygroscopic salts ( $\text{MgCl}_2$ ,  $\text{CaCl}_2$ , and sea salt) showed noticeable changes in the uptake of OH while the others ( $\text{NaCl}$ ,  $\text{Na}_2\text{SO}_4$ , and  $\text{KCl}$ ) did not. This characteristic was determined by the cations, which are responsible for redistribution of surface ions. The most interesting observation was that sea salt reactivity with OH under wet conditions was dictated by  $\text{MgCl}_2$  instead of  $\text{NaCl}$ , its major component. This was explained by the segregation effect of surface ions. The water effect on the OH uptake for mineral dust particles ( $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$ ) was positive resulting in the enhancement of the OH reactivity to a mineral dust surface under wet conditions.

Extending the application to humid conditions, these results can improve atmospheric models for better understanding about the atmosphere, in particular the troposphere. The categorization of organic aerosols with respect to their hydrophilicities will be useful for the models describing polluted urban areas. Furthermore, focus should be given to  $\text{MgCl}_2$  reactivity in relation to the OH budget in the marine boundary layer or coastal urban area under wet conditions.

Secondly, production of  $\text{Cl}_2$  from the heterogeneous reaction of OH on  $\text{NaCl}$  was studied under dry or low RH conditions to complement the current mechanism as reported in the literature, which covers only high RH conditions over the deliquescence RH.

Mass spectra of the gas phase reaction products and XPS characterization of  $\text{Na}(1s)$  provided information about the identification of the products, both gas-phase and solid state, the yield of the product, the effect of RH on product formation, and the reaction mechanism. Since oxidation of  $\text{NaCl}$  by OH produces  $\text{Cl}_2$  even under arid conditions with a yield of approximately 2%, the budget of chlorine-containing species, particularly at the troposphere of high altitude, can be better estimated with these results.

It is expected that our study can significantly improve current atmospheric models for more realistic conditions, providing fundamental information regarding the heterogeneous chemistry of radicals, and suggesting interesting topics for future studies about the interaction between humidity and heterogeneous chemistry, and its mechanism. As a consequence, atmospheric science starting from simple cases for restricted applications will be able to continue progressing to advanced technologies for general application.

## **Chapter 6**

# **Recommendations for Future Study**

The following research topics are recommended for future studies regarding heterogeneous chemistry of radicals in the troposphere.

### 6.1. Drift Tube for Better Sensitivity

This thesis described how water interference on CIMS detection sensitivity was successfully reduced for studies performed under wet conditions. Nevertheless, the maximum relative humidity was limited to  $RH \sim 50\%$  since sensitivity was still sacrificed with increasing relative humidity due to formation of water clusters. Therefore, a drift tube technique is recommended for better sensitivity.

A drift tube is designed for accelerating ions in a flow tube [Hansel *et al.*, 1995; Morrison *et al.*, 2001; de Gouw *et al.*, 2003]. A high voltage ( $\sim 1$  kV) can be applied over an array of electronically isolated metal rings connected with resistors to establish a homogeneous electric field. As a result, the velocity of ions in the drift tube ( $v_d$ ) increases according to the following:

$$v_d = \mu \times E \quad (6.1)$$

where  $\mu$  is the ion mobility and  $E$  is the electric field. The accelerated ion velocity induces a dissociation of the water complex, such as  $OH^-(H_2O)_n$  and  $F^-(HF)_n$ . The resulting enhancement of sensitivity for ion detection under high RH conditions both enables investigation of the RH effect on OH uptake under a wider range of RH values, and reduces the measurement uncertainty of the reaction probability of OH.

### 6.1. The RH Effect on HO<sub>2</sub> Uptake by Surfaces of Tropospheric Importance

With a high mixing ratio (40 ppt), HO<sub>2</sub> radical plays a key role in the oxidation chemistry of the troposphere including heterogeneous chemistry on aerosols.

Therefore, the investigation of RH effect on HO<sub>2</sub> uptake by the surfaces is important to improve tropospheric models. Recently, Remorov *et al.* [2002] reported that extremely low RH (~ 0.5 %) conditions reduced the reactivity of HO<sub>2</sub> on NaCl. For application to real tropospheric conditions, study under high RH (RH ≥ 50%) is required.

The technique employed in the present work can be used to increase the sensitivity to HO<sub>2</sub> detection and for quantification. The only difference would be use of a different reagent ion (F<sup>-</sup>) for ionization of HO<sub>2</sub>.

Along with employment of a drift tube, the RH range can be extended to the deliquescence point of NaCl (RH ~78%). As a result, a study for the release of chlorine-contained species from NaCl upon HO<sub>2</sub> uptake can be performed to explore a potential new source of Cl in the troposphere.
